# Adults with Childhood-Onset Disabling Conditions

This chapter will outline the most common congenital and childhood-onset disabling conditions and the associated secondary conditions encountered as adults. An effort has been made to be comprehensive while emphasizing a practical approach to caring for the adult patient. Medical transition from pediatric to adult care will be introduced as it applies to public health initiatives. We sought to emphasize the many ways that a preventative approach to health and wellness is appropriate in the comprehensive care of adults with childhood-onset disabilities. While we will highlight some aspects of care in this chapter, we want to direct the reader to a more comprehensive treatment of some specific conditions elsewhere in this book, specifically the chapters on osteoporosis, sexuality, women's health, and primary care.

## INTRODUCTION

Children with complex medical and genetic conditions are living longer than was predicted in the past due to better treatments and overall care (1). According to 2000 nationwide census data, approximately 6% or 2.6 million children and youth aged 5 to 15 years have a disability. Currently, 90% of children born with special health care needs reach adulthood (2). Often, the success of excellent pediatric medicine results in young adults who require ongoing, sometimes intensive, medical supervision throughout their lives.

In 2002, the American Academy of Pediatrics, The American Academy of Family Medicine, and the American College of Physicians—American Society of Internal Medicine collaborated on a policy statement to ensure that young people with special health care needs were equipped to move from child-centered to adult-centered health delivery systems (3). In a report from the Maternal and Child Health Bureau (MCHB), published in 2001, three general barriers were identified to health care transitions for young adults: training of qualified providers, funding for health delivery, and bureaucratic obstacles.

In reality, the process of transition should be viewed as a continuum. There are many barriers that challenge families, patients, and physicians alike that greatly complicate the process. The physician receiving transitioning youth must have an

understanding of what some of these barriers entail in order to deliver compassionate care to young adults attempting to make the leap into the adult health care system.

The Medical Home model has been viewed as having primary responsibility for taking charge of transition activities to ensure that young adults with chronic, childhood-onset illness continue to receive the quality of health care that characterized their pediatric years. Thus, the role and responsibility of a medical home has continued to expand with ideals that are difficult to attain without a thorough understanding of the team approach implied in the concept.

The MCHB defines children and youth with special health care needs (CYSHCN) as “those who have, or are at increased risk for having, a chronic physical, developmental, behavioral or emotional condition and who also require health and related services of a type or amount beyond that required by children generally” (4). In 1989, The Omnibus Budget Reconciliation Act (OBRA), Public Law 101-239, amended Title V of the Social Security Act to include the authority and responsibility of MCHB to fully address the needs of all children. In addition, the focus under MCHB for CYSHCN was to provide leadership in promoting a community-based system of services that is family centered, comprehensive, coordinated, and culturally competent, thus building services around a medical home approach. The goals for the Title V CSHCN Program include:

1. Families will partner in decision making at all levels and will be satisfied with services.
2. All CYSHCN will receive coordinated, ongoing, comprehensive care within a medical home.
3. All CYSHCN families will have adequate insurance to pay for the services they need.
4. All children will be screened early and continuously for special health care needs.
5. Community-based service systems will be organized so that families can use them easily.
6. All youth with special health care needs will receive the services necessary to make transitions to all aspects of adult life.

While not all these goals will be the direct responsibility of one clinician, the overall success of medical care delivered in a

chronic care model is hinged on the management of chronic conditions that encompass each of the six goals above.

The Medical Home model addresses barriers to health care access and provides a framework to operationalize efforts to improve health care (see below). The patient and the family are at the center of the defining statement rather than a specific clinician's office. Each of the seven components of a medical home becomes linked to some extent to every medical provider of care for the patient with special health care needs as they manage chronic diseases. Familiarity with these components is the first step toward increasing the medical home approach in specialty care.

The components of the Medical Home Initiative (5) include:

- Access to care
- Family-centered care
- Cultural responsiveness
- Continuity of care
- Comprehensive care
- Compassionate care
- Coordination of care

*Access to care* refers to whether the patient can receive the health care services they need when they need it, even outside regular business hours and includes having a way to pay for needed services. *Family-centered care* is health care that takes into consideration the requests of the family and respects them as partners in the health care decision making of the medical home concept. *Cultural responsiveness* considers the values and beliefs that the family and the patient bring with them into the medical encounter. *Continuity of care* implies communication among all health care providers, especially primary care physicians and specialists. *Comprehensive care* is medical care that includes primary medical and developmentally appropriate care, dental care, mental health services, as well as crisis and chronic illness management. Application of routine primary care guidelines is also a component of comprehensive care. *Compassionate care* considers the concerns of the family and how the diagnosis of the patient may affect others. *Coordination of care* embodies the day-to-day development of a health care plan, including the transition plan, for a patient and ensures its implementation.

With the medical home concept at the hub of chronic illness care, rehabilitation professionals will be challenged to provide leadership in long-term follow-up of our patients. Preserving wellness and independence is the ultimate goal, not necessarily episodic/acute care management. Preservation of quality-of-life indicators, as individually applied to each patient, while postponing functional decline is an important role.

As young adults with disabilities transition to more independence, physicians need to educate patients and their families about potential age-related changes and medical issues. There is a growing interest in the literature about aging issues and secondary conditions among persons with congenital and childhood-onset disabling conditions. Differentiating between primary, associated, and secondary conditions may help the clinician categorically organize a patient's care goals.

The *primary condition* is self-explanatory. It is the diagnosis that initiated entering into medical care from the point of evaluation during gestation, infancy, or childhood. *Secondary conditions* are impairments, functional limitations, disabilities, diseases, injuries, or other conditions that occur during the life of a person with a disability, in which the primary disabling condition is a risk factor for that secondary condition or may alter the standard intervention for prevention of treatment of any health condition (Syracuse Conference, 1994). A disabling condition, such as a spinal cord injury (SCI) or cerebral palsy (CP), is not synonymous with illness or disease. People with disabilities are generally healthy, and one should not expect a decline in health and function as they mature. Therefore, physicians must have an index of suspicion for such conditions that may have onset in late adolescence or adulthood or be insidiously progressive. They may include progression of pathology or impairment, either through complications or through the aging process. Commonly reported secondary conditions include pain, contractures, recurrent urinary tract infections, pressure sores, and osteoporosis. *Associated conditions* or residual impairments are conditions that result from the defect, injury, or disease and often may be considered primary impairments depending on their severity. An example is neurogenic bowel/bladder in patients with spina bifida. *Comorbidities* are medical conditions unrelated to the primary disabling conditions such as adult-onset diabetes or hypertension in a patient with CP.

Health perception is an individual determination and is affected by personal expectations, experiences, sense of vulnerability, support, and locale. The World Health Organization (WHO) defines *quality of life* (QoL) as "an individual's perception of their position in life in the context of the culture and value systems in which they live, in relation to their goals, expectations, standards, and concerns" (6). Health-related QoL is a broad concept affected in a complex way by an individual's physical health, psychological state, personal beliefs, social relationships, and their relationship to salient features of their environment. Although it is widely acknowledged that this is an area of concern for adults with chronic disabilities, there are limited studies that have systematically assessed QoL in these individuals, particularly those with neuromuscular disorders (7). This may be due in part to the fact that QoL is perceived as a somewhat vague entity that many people are concerned about, but something that nobody clearly knows what to do about. These issues are important in examining disability in adults who are survivors of disabling childhood disorders.

What follows is an overview of common chronic conditions and specific management recommendations for care.

## SPINAL CORD INJURY

### Background

When SCI occurs at a young age, there are unique medical complications that can significantly impact the adult years. Transition into adult care requires knowledge of these issues

as well as a multidisciplinary treatment approach. Recent data suggest that adults with childhood-onset SCI have a slightly lower life expectancy compared with those who sustained their injury as an adult. However, those with childhood-onset SCI are still living long lives with life expectancy estimates of approximately 83% of normal for those with minimal deficit incomplete injuries compared with 50% of normal in non-ventilator-dependent tetraplegics (8).

According to the 2006 Annual Statistical Report for the Model SCI Care Systems, approximately 253,000 people are living with SCI in the United States, with 11,000 new cases reported each year. Less than 20% of SCI occurs in children and adolescents with approximately 5% of those less than 15 years of age (9).

Adults with childhood-onset SCI may experience acceleration of the aging process because of diminished physiologic reserves and increased demands on functioning body systems. Secondary medical conditions are extremely common in adults with pediatric-onset SCI and can negatively impact a satisfying adult life. The most common conditions include pneumonia, pressure ulcers, and genitourinary issues (10). Long-term management of adults with SCI also needs to include ongoing evaluation of psychosocial issues such as life satisfaction, living situation, employment, and education.

## Problem-Based Approach to Management

### Pulmonary

Respiratory complications are the leading cause of death in persons with spinal cord injuries. It has been found that 72.3% of deaths from respiratory causes are due to pneumonia. There is a well-documented association between increased risk of pneumonia and higher level of SCI (11). Inspiratory capacity is decreased in persons with higher level injuries, which can lead to microatelectasis, dyspnea with exertion, and (in those with more severe impairments) respiratory insufficiency. Muscles of expiration can be impaired, which can impact cough effectiveness and clearance of secretions with susceptibility to lower respiratory tract infections (12). The high incidence of scoliosis in childhood-onset SCI may influence pulmonary function as adults, particularly when curves are large and not surgically corrected. Where appropriate, respiratory muscle strength training, cough-assistive devices, and noninvasive ventilation need to be considered. Vaccinations against influenza and *Streptococcus pneumoniae* are recommended. Smoking should be strongly discouraged due to the potential adverse affect on respiratory function.

### Bladder

Renal failure was, in years past, the leading cause of death in persons with SCI, but this is no longer the case due to significant advances in urologic management. However, urinary tract infections continue to be a high cause of morbidity. UTIs have been reported in 74% of adults with childhood-onset SCI (13). Greater neurologic impairment has been shown to be a risk factor for UTI in both childhood- and adult-onset SCI (13,14). UTIs may lead to bladder and renal calculi, pyelonephritis, and vesicoureteral reflux. The use of prophylactic antibiotics

has not been well supported (15). Nephrolithiasis is a common problem in persons with SCI and can contribute to renal failure. Risk factors that can contribute to UTIs and resultant stone formation are vesicoureteral reflux, chronic catheterization, detrusor-sphincter dysfunction, immobilization hypercalciuria, and prior kidney stones (16). The incidence of bladder cancer in SCI is 16 to 28 times higher than that of the general population. Risk factors for bladder cancer are chronic indwelling catheters, smoking, and renal and bladder stones. Gross hematuria should raise concern for bladder cancer (17).

Routine screening of the urinary tract is necessary to decrease morbidity, but there is a lack of consensus on the surveillance tool to use. Most physicians recommend a yearly renal ultrasound for evaluation of the upper tracts, whereas more than half routinely use urodynamic studies for evaluation of the lower tract (18). A survey of physicians found that the combination of clean intermittent catheterization (CIC) plus anticholinergic agents is the favored method for hyper-reflexic bladder management, whereas CIC alone is preferred for the areflexic bladder (18).

### Bowel

There is a high prevalence and wide spectrum of gastrointestinal complaints in SCI.

Bowel incontinence is a commonly reported complication in adults with childhood-onset SCI (13). Bowel dysfunction tends to increase with duration and severity of SCI (19). Chronic constipation can lead to megacolon, which has been found more commonly in those with longer duration of injury and older age (20). Sixty percent of adults with childhood-onset SCI report a bowel program exceeding 30 minutes (21). Thus, incontinence and prolonged bowel program duration can greatly impact QoL.

### Skin

Pressure ulcers are one of the most common secondary conditions experienced by adults with childhood-onset SCI and have been reported in 44% of persons (13). They are associated with significant morbidity and have great impact on adult outcomes including perceived health status, community integration, and life satisfaction (22). They are also one of the leading causes of rehospitalization (11). The financial burden of such a hospitalization can be tremendous. Many studies have shown that prevalence of pressure ulcers increases with time postinjury. Those with complete injuries, previous pressure ulcers, and older age tend to have a higher risk (23–25). Adults who have sustained an SCI as a child are more likely to develop hip subluxation, which could result in a pelvic obliquity and predisposition to pressure ulcers (26). Individuals need to be vigilant about skin checks and pressure relief. Seating systems and orthotics need ongoing monitoring and need re-evaluation in the event that a new pressure sore develops.

### Pain

There are many potential sources of pain in adults with chronic spinal cord injuries. According to Vogel and colleagues in 2002, pain in adults with childhood-onset SCI has been

reported as high as 69% (22). Adults with SCI report pain of a musculoskeletal nature most frequently, followed by neuropathic and lastly visceral (27). Neuropathic pain has been found to be less common in persons less than 20 years at the time of injury (28). Many studies have shown that persons with SCI and associated pain have decreased life satisfaction (29,30). Thus, it is imperative that clinicians investigate and manage pain appropriately.

Musculoskeletal pain is common, particularly in the shoulders. Vogel et al. found that 48% of adults with childhood-onset SCI report shoulder pain (22). It has been shown that prevalence and intensity of shoulder pain in wheelchair users is significantly higher in persons with tetraplegia (31). Wheelchair users may be more prone to pain due to the repetitive use of their upper extremities during wheelchair propulsion, transfers, and self-care. There is also evidence that the prevalence of shoulder pain increases over time (32). A home exercise program of stretching and strengthening has been shown to be effective in decreasing pain and improving function and satisfaction in wheelchair users (33).

Peripheral nerves can be a source of pain. Carpal tunnel syndrome has been reported to be the most common upper limb neuropathy, and sciatic neuropathy the most common lower-limb abnormality. Persons with tetraplegia developed more frequent peripheral nerve lesions than paraplegics (34).

Pain can result in increased spasticity which can further increase pain. Management needs to focus on the underlying cause, but pain may improve with reduction in spasticity such as with antispasticity medications or focal injections.

Management includes evaluation of ergonomics and biomechanics of functional tasks, equipment, and lifestyle in addition to traditional interventions such as medications, manual medicine, trigger point injections, physical therapy, and tone management.

## Neurologic

A syringomyelia must be considered when there is progressive neurologic deterioration after a stable period. It has been found to occur more often in those with complete injuries and is often associated with arachnoiditis (35). Clinical symptoms can include pain, weakness, sensory disturbance, and autonomic dysfunction. It can occur months to years after SCI. Referral to neurosurgery should be made for surgical considerations.

## Autonomic Dysfunction

Autonomic dysreflexia (AD) is a potentially life-threatening complication of SCI in which uncontrolled sympathetic outflow occurs in those with lesions above T6 in response to a noxious stimulus such as bladder or bowel distension. The hypertension and compensatory bradycardia that result can be life threatening if not promptly recognized and treated. AD has been reported in 42% of adults with childhood-onset SCI (13). This is higher than that reported in adult-onset SCI (23). Women need to be educated about the risk of AD during

pregnancy and nursing. Most can have successful vaginal deliveries but need appropriate monitoring and epidural anesthesia early in labor (36).

## Osteoporosis

Fractures may be asymptomatic in persons with SCI and impaired sensation may delay treatment. Complications including impaired fracture healing, pressure sores, infection, and osteomyelitis present an additional cause of morbidity.

Osteoporosis is a well-known consequence of SCI. Fracture prevalence has been reported to increase with time, from 1% in the first 12 months to 4.6% in individuals greater than 20 years postinjury (37). As with other disabilities, fractures are frequently associated with only minor trauma. Bone loss occurs rapidly after an SCI with the majority of loss occurring in the lower extremities. Trabecular bone is more affected than cortical bone in the SCI population. There is dissociation between bone mineral density (BMD) in the hip and the spine. It has been found that there is a relative maintenance of BMD in the lumbar spine with significant demineralization of the proximal femur (38). This is consistent with the finding that fractures occur primarily in the lower extremities and not in the vertebral bodies.

The accrual of bone mass is accelerated during puberty, and this process is interrupted in childhood-onset SCI (39,40). In a study of adults with childhood-onset SCI, DXA studies showed that the BMD at the lumbar spine was normal but greatly decreased at the proximal femur region. Also, persons with higher level injuries (C2 to T6) had higher BMD (40). This reinforces the need for aggressive prevention and treatment of osteoporosis early on.

DXA is the gold standard for evaluating BMD in children and adults. If possible, DXA scans should be done using the same machine each year to avoid variations in test results caused by different equipment. Adequate intake of calcium and vitamin D is important. The use of alendronate has been shown to have a positive effect on BMD in persons with SCI, but more research is necessary (41). Functional electrical stimulation (FES) has not been shown to change BMD significantly (42). Consultation with an endocrinologist experienced in the management of metabolic bone disease can be extremely helpful.

## Cardiac

Age is clearly an important risk factor for cardiovascular disease in the nondisabled population as well as those with SCI. However, it has also been shown that total cholesterol and LDL are higher while HDL is lower in those with increased duration postinjury (43). It has been postulated that SCI bestows an additional cardiac risk over that with age due to enforced sedentary lifestyle and that this increases with duration post injury (44).

With cardiovascular disease becoming a leading cause of mortality in SCI, discussing modifiable risk factors such as activity level, weight control, smoking, and alcohol consumption is extremely important.

### Depression/QoL

Depression is a significant concern in adults with pediatric-onset SCI as depressive symptoms have been reported in 27% (45). Depression has been associated with lower QoL, less community participation, and more medical complications. When evaluating life satisfaction, there appears to be no significant difference between men and women, but those with tetraplegia are significantly less satisfied than those with paraplegia (46). Fortunately, for most, perceived QoL among persons with long duration spinal cord injuries is high and relatively stable over time (47).

## CEREBRAL PALSY

### Background

CP is the most common form of chronic physical disability of childhood. CP refers to a heterogeneous group of disorders that describe impairment in the development of posture and motor control as a result of a nonprogressive lesion of the developing central nervous system. No assumptions should be made with regard to cognitive ability based on motor functioning alone. Many adults with CP live and work independently in the community and lead full, productive lives (48). However, motor performance can deteriorate once adulthood is reached due to the impact of various secondary conditions. It has been found that follow-up with health and rehabilitation services is dramatically reduced once adulthood is reached (49).

The life expectancy in CP is reduced depending upon the severity and other associated health conditions. Several studies have demonstrated that survival is influenced by the presence of severe mental retardation and reduced mobility (50–52). The key predictors were lack of basic functional skills including mobility and feeding. Adults lacking these skills had much reduced life expectancies, as short as 11 years for the worst functioning groups. By contrast, survival of high-functioning adults was close to that of the general population. Life expectancies of adults of a given age can differ by 40 years or more, according to their functional level (51).

In the modern era of molecular genetics, any child or adult with a diagnosis of CP should be considered a candidate for periodic evaluation to better describe their underlying condition. The time of transition from pediatric medicine to the adult health care system is an ideal time to relook at the individual from a diagnostic perspective.

### Problem-Based Approach to Management Pain

Pain has been recognized as a serious secondary problem in adults with CP. Chronic pain has been reported in 30% to 67% of adults, with back and lower extremities being the most commonly affected sites (53,54). Adults with dyskinesia tend to report more cervical pain (55). Fifty percent of adults report pain in more than one body part (48). It is plausible that improper biomechanical forces due to spasticity, contractures, and physical stress could lead to overuse injuries,

but this has not been widely studied in CP (55). Several studies have documented the impact of chronic pain on the lives of adults with CP. Many adults experience limitations in their activities, social withdrawal, decreased self-esteem, depression, loss of roles, relationship strain, and emotional distress that leads to a cycle of despair and hopelessness (56,57). Deterioration in function can also be seen as a result. Assessment of pain can be challenging in those with severe cognitive impairment; thus, changes in behavior, posture, spasticity, or range of motion should heighten awareness.

Spasticity has been shown to play a significant role in the development of chronic pain in persons with CP. Spasticity can result in muscular and joint pain, and spasticity often increases in response to the pain. It has been found to be associated with higher rates of osteoarthritis, dislocation, pain, and pressure ulcers (58). Tone management including antispasticity medications, botulinum toxin, phenol neurolysis, and intrathecal baclofen can be helpful. In a study of adults with spasticity, including CP, botulinum toxin combined with therapy improved function and activities of daily living (ADL) in up to 91% while pain was improved in 90% (59).

Treatment of pain is challenging and it has been found that the majority of adults with CP and chronic pain do not seek help from health care providers for pain management (60). One study demonstrated no significant change in pain intensity over 2 years despite an increased use of varied pain treatments (61). Often, once an adult develops chronic pain, there may be few treatments that will be effective (56). Multidisciplinary and cognitive behavioral therapies have proven beneficial to patients with CP-related chronic pain. Coping in this population has been shown to improve when the training is focused on teaching and encouraging patients to learn to maintain their daily tasks despite pain (56).

### Musculoskeletal

It has been suggested that adults with CP may show musculoskeletal or performance changes typical of advanced aging earlier than their nondisabled peers (55). Disabilities that have a long duration can produce excessive wear and tear on the muscular, skeletal, and other body systems.

Contractures are common in adults with CP and may significantly contribute to joint pain, sitting intolerance, difficulty with ambulation and transfers, and pressure sores. Eighty percent of adults report contractures with 33% of these occurring in 2 to 3 joints (48). Hip adduction and flexion contractures and windswept deformities create pelvic obliquities and tend to be associated with hip pain as well as problems with perineal care as reported by Noonan and colleagues. Subluxed or dislocated hips can remain problematic in adults with CP. By adulthood, severity of progression can preclude many interventions that may have been suitable early on, but what, if any, management is needed remains debatable (62). The presence of a unilateral hip dislocation often creates a pelvic obliquity that can result in sitting imbalance, hip pain, and pressure ulcers. The reported incidence of hip pain in adults with varied severity of CP is 18% to 50% (58,62,63). It is

plausible that those with less severe involvement may be able to report pain more consistently and accurately. Radiographic evidence of osteoarthritis has been found to strongly correlate with dislocated and subluxed hips, but pain is not necessarily an associated factor (58). If a dislocated hip becomes painful in adulthood or adduction contractures interfere with ADLs or sitting, a proximal femoral resection can be performed with a good outcome (62). Total hip arthroplasty for painful, refractory, subluxed, or dislocated hip has been shown to relieve pain and improve function in 94% of adults with various severities of CP, but its lifelong efficacy is not known (64).

Scoliosis is a significant problem for many youth and adults with CP. Severe curves can be associated with pelvic obliquity, pressure sores, and functional decline (65). Few studies have evaluated the natural history of scoliosis in adults with CP, and it has been shown that there is a high risk of progression with curves of 40 degrees at skeletal maturity (65,66). Average progression rate has been shown to range from 3 to 4.4 degrees per year, depending on function (65). Cardiopulmonary compromise can also occur and is associated with severity of curve and age (67). Surgical correction in these adults may improve respiratory function but outcomes are variable (68). Close surveillance of pulmonary function is needed, and it is important to continually monitor seating, skin integrity, and comfort.

Cervical myelopathy is a potentially devastating secondary condition in adults with athetoid CP. Cervical disc degeneration tends to occur at a younger age and may be attributable to abnormal excessive neck motion in this population (69). Awareness should be heightened with onset of neck pain, significant change in function, or change in neurologic exam. Surgical treatment may prevent further, often catastrophic loss of function, but recovery may not be complete. Short-term surgical outcome is favorable; neurologic deterioration or development of kyphosis can occur greater than 5 years and occasionally greater than 10 years postoperatively (70). Long-term follow-up is essential and postoperative management planning should accommodate change in functional capabilities and care needs.

### **Osteoporosis**

Many children and adults with CP have decreased BMD and a propensity to fracture with minimal trauma (71,72). Reduced BMD is associated with prior fractures, use of anticonvulsants, feeding difficulties, more severe involvement, and increasing age (71). Use of calcium and vitamin D should be standard in those at risk for immobility-related osteoporosis. Studies on pamidronate in children and adolescents with CP have shown benefit, but long-term effects are not known (73,74).

### **Bowel/Bladder**

Constipation and decreased colonic motility have been shown to be related to ambulatory function in children (75), and it is plausible that these issues persist into adulthood. An increased incidence of gastrointestinal complaints has been reported in adults with CP (55,76).

A number of the adults have urinary complaints due to difficulties with toilet accessibility and possible neurogenic

bladder (55). Those with recurrent UTIs or incontinence tend to have abnormal urodynamics, and these findings increase with higher Gross Motor Function Classification System (GMFCS) level (77).

### **Function**

Aging and development of secondary conditions can impact motor function and ADLs in adults with CP. It has been shown that the GMFCS level observed around age 12 is highly predictive of adult motor function (78). By age 25, improvement in ambulation is unlikely and decline more likely (79). For those persons who are ambulatory when they reach adulthood, there is a significant decline in ambulation, especially in late adulthood, and few of the 60 year-olds who walk well maintain this skill over the following 15 years. Older persons often lose the ability to dress themselves. Speech, self-feeding, and the ability to order meals in public are often preserved. A majority of young adults live in their families' home or in small private group homes, while only 18% of the 60 year-olds live independently or semi-independently, and 41% reside in medical care facilities (80).

## **SPINA BIFIDA**

### **Background**

Neural tube defects are the second most common type of birth defect with a birth incidence of 1:1,000 live births (81). Neural tube defects can range from spina bifida occulta to anencephaly. Spina bifida occulta refers to a posterior element defect of the spine covered by skin and no protrusion of neurologic elements. Generally, there are minimal neurologic deficits. Myelomeningocele is a defect in the posterior spinal elements with neural structures found within the thecal sac leading to significant neurologic deficits. Neural tube defects are complex traits with multifactorial etiology encompassing both genetic and environmental components (82).

Health management for adults with spina bifida has gathered increasing attention. The Spina Bifida Association of America has led an effort toward better education of patients and health care providers working with this patient population. Improved management of neurogenic bladder dysfunction and hydrocephalus has increased the survival into early adulthood to 75% (83,84).

### **Problem-Based Approach to Management Bladder**

The majority of adults require some type of bladder management program. Sixty percent of young adults in one study reported urinary incontinence regardless of the type of management used (85). This includes intermittent catheterization, use of indwelling catheters, urinary diversion, and artificial sphincters. It has been found that most young adults use intermittent catheterization (86,87). Anticholinergic and alpha adrenergic medications are a mainstay of conservative management, and up to 40% of young adults have reported using pharmacologic treatment (84,87).

Renal failure and its complications remain the most prevalent cause of morbidity and mortality in adults with spina bifida (88). The rate of renal failure in adults with spina bifida has declined significantly due to appropriate intermittent catheterization techniques. Risk factors include chronic urinary tract infections and nephrolithiasis. Peritoneal dialysis can be complicated by ventriculoperitoneal shunts or urinary stomata, but recent studies have shown that having a shunt is not an absolute contraindication (89). Renal transplantation has been shown to have good outcomes (88). Adults with spina bifida and neurogenic bladder have an increased risk of bladder cancer, and this may be influenced by bladder augmentation (90). Careful surveillance is required.

Annual renal function tests, blood pressure, ultrasound, and urodynamics are important tools to monitor urologic function (91). Any change in bladder function should be thoroughly evaluated in the adult patient, as a change could also indicate a neurologic abnormality.

### **Bowel**

To some extent, all adult patients with spina bifida have some degree of bowel dysfunction. Young adults tend to report less problems with fecal incontinence compared to urinary incontinence (87). The management of neurogenic bowel changes over time as gastric motility is altered with age. Treatment of bowel dysfunction includes medications, dietary modifications, and surgical interventions such as cecostomy buttons and antegrade continence enema (ACE) procedures (92). It has been shown that those using ACE management reported significantly improved fecal continence compared with conventional management, negating the need for retrograde rectal enema and digital extraction (93). Poor compliance with the bowel program may lead to increased numbers of urinary tract infections, incomplete bladder emptying, improper draining of VP shunts, colon cancer, abdominal pain or cramping, chronic constipation, megacolon, skin breakdown, and limited social/professional experiences (94).

### **Skin**

Nearly half of adults have some history of skin breakdown (95). The presence of insensate skin and changes in fat and muscle distribution contribute to the high incidence of pressure ulcers (92). Lower extremities are a common site for ulcers due to poorly fitting orthotics and improper biomechanics created by muscle imbalance and associated foot deformities. Those dependent on wheelchair mobility are susceptible to pressure in the ischial and sacral areas. Frequent pressure relief and as appropriate cushion are imperative, and pressure mapping may be necessary for more complex cases. Surgical closure or even amputation may ultimately be necessary. The high economic burden associated with pressure ulcers and osteomyelitis is significant (96). Burn prevention is also a lifelong issue given insensate skin. Patients should be advised to perform routine skin checks and personal hygiene should be emphasized as this is an important part of maintaining good skin health. Given frequent exposure to medical products containing latex,

screening periodically for signs and symptoms of latex allergy is recommended. Adults may have a higher rate of reactions including anaphylaxis (97).

### **Neurologic**

Nearly 90% of young adults with spina bifida have a ventriculoperitoneal shunt (83). Lifelong follow-up is necessary in persons with shunts. Even though the incidence of shunt malfunction is greatest during the first year after the shunt is placed, and the majority of shunt revisions occur in the first two decades of life, it has been reported that 4% of emergency shunt revisions are performed in the third decade of life (98). Symptoms may include insidious onset of cognitive decline or chronic headaches in addition to the typical neurological symptoms seen in children (99). Adults should have routine neurologic examinations as well as periodic computed tomography scans. Although shunt revision remains a common treatment, one center has found the use of neuroendoscopic third ventriculostomies to be more successful in adults than children (100).

Spinal cord tethering may occur at any age. Symptoms include any change in neurologic status or bowel or bladder function, increasing orthopedic deformities, or gait changes. In contrast to children, adults may have an inciting traumatic event, pain in sacral dermatomes, and more subtle cutaneous abnormality (95). Evaluation includes magnetic resonance imaging and possibly urodynamics. As in children, imaging alone does not justify detethering as the conus will be low lying in all previously untethered lesions.

Adults with a previously treated tethered cord can present years later with symptoms of Chiari malformation. Several studies have shown a high prevalence of the Chiari/hydrosyringomyelia complex in adults with spina bifida with symptoms including headaches, upper limb weakness, sensory changes, ataxia, and lower cranial nerve palsies. Respiratory and swallowing difficulties are not reported as commonly as in children (86). Evaluation includes magnetic resonance imaging. Treatment with decompression and or shunting should be done early to avoid further neurological compromise (86).

### **Musculoskeletal**

Those children with spina bifida who are still ambulatory as teenagers tend to remain so into their adult years (83). It is described that deterioration of ambulation can occur in adults due to change in the neurologic level of lesion, spasticity, knee and hip flexion contractures, low back pain, lack of motivation, as well as major events such as stroke (101). Adults often develop improper biomechanics created by muscular imbalance that can result in hip and knee pain. Charcot joints can also develop due to these imbalances and impaired sensation. In contrast, those who are wheelchair dependent are susceptible to repetitive upper extremity movements associated with wheelchair activities and transfers. One might expect shoulder pain and peripheral nerve injuries to be common in adults with spina bifida, but pain in this population is not as well described as in those with SCI (32). One study found that 56% of children and adolescents reported experiencing pain in varied sites once a week or more often (102).

### Osteoporosis

It is known that fracture rate in children with spina bifida is higher than in the general population (103), but it is less known how this translates into the adult years. In adults with spina bifida, neither fracture rate nor osteoporosis has been well studied. A recent study actually showed a higher incidence of fractures in adolescents than adults (104). One study examined the prevalence of osteoporosis and osteopenia in adults with myelomeningocele using DXA and found that 33% had osteoporosis in at least one site and secondary conditions were associated with lower BMD (105).

Treatment includes appropriate calcium and vitamin D supplementation. Data on bisphosphonates are lacking.

### Nutrition

Maintaining an ideal body weight is of critical importance in adults with spina bifida when considering prevention of long-term effects of obesity. Complications of obesity include hypertension, diabetes, cardiovascular disease, hyperlipidemia, obstructive sleep apnea, and osteoarthritis. Nutritional counseling should not only include dietary recommendations but also include information on physical activity.

### Sexuality

Adults with longer duration of disability tend to report significantly more positive feelings about their sexuality (106). The majority of young adults with spina bifida report being sexually active (107). Data on the impact of sexual function on QoL in this population are inconsistent (107,108). It has been found that urinary incontinence is a negative predictor of sexual activity and that women with hydrocephalus are less likely to be sexually active (107). Sexual health needs to be enforced in women with spina bifida. Annual Pap smears and mammograms are needed although access and attitudinal barriers can make this challenging. Information on contraception and STDs also needs to be provided. Women with spina bifida are able to carry pregnancies to term; however, awareness should be increased as distal shunt malfunction can occur during the third trimester (95). Infertility issues such as erectile or ejaculatory dysfunction need to be addressed by physicians. Erectile dysfunction in spina bifida has been well studied, and while 85% of men achieve psychogenic erections and 88% are able to ejaculate, only 54% experience rigidity at erection (109). Sildenafil (Viagra) has been shown to improve erectile function in 80% of men with spina bifida (110). Counseling regarding the increased risk of neural tube defects in the children of those with spina bifida is important.

## NEUROMUSCULAR DISEASE

### Background

Patients with neuromuscular disease (NMD) present many complex transition issues and problems. Many issues arise in early childhood and increasingly more children are living into adulthood. Duchenne muscular dystrophy (DMD) is the

most common form of childhood-onset muscular dystrophy. It is estimated that DMD affects 1/3,500 to 1/6,000 live born males (111). DMD and Becker muscular dystrophy (BMD) form a spectrum of clinical severity, and together are referred to as *dystrophinopathies* (112). DMD is an X-linked recessive disorder that is characterized by a progressive weakness of skeletal muscle. The lack of dystrophin, a muscle structural protein, results in an unstable muscle fiber membrane and impaired muscle homeostasis (113).

### Problem-Based Approach to Management

#### Pulmonary

Respiratory disease is a major cause of morbidity and mortality in DMD. Assisted ventilation has had a profound effect on the natural history. Most caregivers have changed to a more aggressive and supportive approach. The American Thoracic Society (ATS) has developed a consensus statement entitled: "Respiratory Care of the Patient with Duchenne Muscular Dystrophy" (114).

DMD is associated with a gradual loss of muscle function over time, leading to ineffective cough, decreased ventilation, and respiratory insufficiency. These complications are generally preventable with careful serial assessments of respiratory function. Routine evaluations should include oxyhemoglobin saturation, spirometric measurements of FVC, FEV1, maximal midexpiratory flow rate and maximum inspiratory and expiratory pressures, and peak cough flow (115).

Effective airway clearance is critical to prevent atelectasis and pneumonia. Cough peak flows correlate directly with the ability to clear secretions, and values below 160 L/min and/or maximum expiratory pressures below 60 cm H<sub>2</sub>O have been associated with ineffective airway clearance (116). Many techniques have been developed to overcome an ineffective cough in patients with neuromuscular weakness. These include manual techniques such as glossopharyngeal breathing, air stacking, intermittent positive pressure, and mechanical ventilation.

Mechanical insufflator-exsufflators simulate coughing by providing a positive pressure breath followed by a negative pressure exsufflation (117). This device has been shown to be effective and well tolerated with occasional side effects of transient nausea, abdominal distention, bradycardia, and tachycardia. The ATS Committee strongly supports the use of mechanical insufflation-exsufflation.

Persons with DMD have increased risk for sleep-disordered breathing, including hypopnea, central and obstructive apnea, and hypoxemia. Treatment of these pulmonary complications with noninvasive ventilatory support can improve QoL and reduce the high morbidity and early mortality (118). Nasal intermittent positive pressure ventilation with bilevel positive airway pressure generator or mechanical ventilation can be used in the treatment of sleep-disordered breathing and nighttime hypoventilation (119). Oxygen supplementation is not recommended without ventilatory assistance. Daytime ventilation should be considered when waking PCO<sub>2</sub> exceeds 50 mm Hg or hemoglobin saturation remains less than 92% at sea level while awake (114).

Full-time ventilation can be provided when other device interfaces are poorly tolerated or the patient lacks sufficient oromotor and/or neck control to use a mouthpiece. The advantages of a tracheostomy include a more secure interface, ability to provide higher ventilator pressures in patients with intrinsic lung disease, or severe reductions in chest wall compliance. The potential complications include increased secretions, increased aspiration risk, and infection.

### Cardiac

Cardiac involvement is the second most common cause of death in patients with DMD, with 10% to 20% dying of cardiac failure. The heart is almost always affected by progressive cardiomyopathy. All patients should have regular cardiac evaluations with annual electrocardiograms and echocardiograms (120). Dilated cardiomyopathy primarily involves the left ventricle. Right ventricle failure can result from respiratory failure and pulmonary hypertension. The patients are also at risk for ventricular arrhythmias.

Initiating therapy at the presymptomatic stage of left ventricular dysfunction is known to delay the onset of cardiac failure and improve prognosis. Combination therapy with an angiotensin-converting enzyme (ACE) inhibitor and nonselective beta-blocker is recommended (121). There are some retrospective data suggesting that cardiac involvement is less frequent in patients treated with deflazacort (122).

### Nutrition

Malnutrition and obesity are common problems in young adults with DMD. Regular evaluations of ideal body weight and body mass should be provided by a nutritionist especially if the patient is on steroid medication. Swallowing should be monitored clinically and an evaluation for dysfunctional swallowing performed if there is a history of choking or dysphagia (123). A video fluoroscopy may assist to prescribe safer swallowing techniques. When adequate nutrition cannot be maintained, gastrostomy tube placement and enteral feedings are highly encouraged.

### Osteoporosis

Osteoporosis and fractures are common in patients with DMD especially those on steroid medication (122). Long bone fractures occurred in 38.7% during steroid therapy compared with 26.5% in the nonsteroid group (124). Of the fractures occurring in the steroid group, 84.9% were in the lower extremity. Patients with DMD should have dietary counseling and baseline DXA scanning (125). Calcium and vitamin D supplements are recommended. The role of bisphosphonates and other bone-sparing agents is encouraging (126).

### Pain

Pain is a significant problem for most patients with NMD, although it is not typically a direct consequence of the disease (127). Most commonly, the pain is caused by immobility. This may lead to adhesive capsulitis, low back pain, pressure

areas on the skin, and generalized myofascial pain (127). It has been found that the frequency and severity of pain reported in slowly progressive NMDs is significantly greater than that reported by the general U.S. population (128). A significant correlation has been shown between increased pain and lower levels of general health, vitality, social function, and physical role (128). Pain assessment needs to be a standard aspect of care.

### End-of-Life Planning

End-of-life directives are a critical part of anticipatory care. Respiratory failure can occur suddenly or in association with a prolonged process. Education about ventilatory and palliative options should be discussed prior to ventilatory failure (129). Physicians have an ethical and legal responsibility to disclose all treatment options, including long-term ventilation. There is evidence that health care professionals underestimate the QoL of ventilator-dependent people with DMD. Patient/families choosing to forgo long-term ventilation must receive palliative care and guidance.

## OSTEOGENESIS IMPERFECTA

### Background

Osteogenesis imperfecta (OI) is a group of disorders characterized by fractures with minimal or absent trauma, dentogenesis imperfecta, and hearing loss. The spectrum of the phenotype has a broad range. At the most severe end of the spectrum, perinatal death may occur. Other manifestations include individuals with severe skeletal deformities, mobility impairments, and very short stature to nearly asymptomatic individuals with a mild predisposition of fractures, normal stature, and normal life span. Inheritance has been documented to be autosomal dominant or autosomal recessive. Mutations in COLA1 or COLA2 characterize the underlying molecular defect for OI types I to IV. Most mutations are de novo. Adults with OI need to cope with the musculoskeletal concerns associated with OI and also manage the same health issues as other adults (130).

Most adults with OI experience a decrease in the rate of fractures after puberty. Tendon, muscle, and joint problems may be aggravated with time, and hearing loss may become significant (131). Vigorous and consistent medical care remains as important as it was during childhood.

### Problem-Based Approach to Management

#### Osteoporosis

Maintaining bone mass is a priority for adults with OI because fracture risk is, in part, related to bone density. An initial DXA test may be obtained at any age and then yearly thereafter. Bone density can decline as a direct result of OI, from immobilization associated with casts or limited weight-bearing activity, and from age-related changes in bone and the endocrine system. Treatments can include calcium and vitamin D supplements, drug therapies including oral or intravenous bisphosphonates,

diet, and exercise (132,133). There is limited experience with adults and use of IV bisphosphonates (134). Smoking, overuse of alcohol, and certain medications, including cortisone-like steroids, can also negatively impact bone health.

### Musculoskeletal

Adults often report pain in their lower back and hips. This can be the result of compression fractures of the spine, scoliosis, or joint deterioration. Other problems can include nonunion fractures and low muscle strength. Knee pain, ankle instability, and rolling in of the ankle are frequent complaints of people with OI. These problems can be a result of joint laxity which subjects knee and ankle joints to pressure over the years. Leg lengths may differ due to a history of previous fractures. Exercise or orthotic devices to improve hip, knee and ankle alignment, and back or joint surgery may provide relief. Heel lifts and firm ankle supports can limit wear and tear on the joints and improve walking comfort (135). Joint replacement surgery may be a treatment option for some, but not all, adults with OI who have joint problems (136).

### Pain

Adults may experience pain from old fractures, or compression fractures of the spine related to either OI or osteoporosis (131). Unstable joints may increase degenerative changes, which are the source of pain in many individuals. Pain management may include lifestyle adjustments to protect the spine, medications, and alternative treatments (136). Adults should be wary of increasing the strength of pain medication to the point where it depresses respiration or consciousness. Reduced consciousness can increase the risk of falls and fractures.

### Pulmonary

Type III and type IV OI and those individuals with significant curvature of the spine may have restrictive lung disease due to decreased chest volume, chronic bronchitis, and asthma. Rib fractures and muscle weakness also may contribute. Sleep apnea is a related problem for some adults with OI and can be diagnosed with an overnight sleep study. Exercise to promote deep breathing, regular testing of pulmonary function, and use of supplemental oxygen can help manage pulmonary function. BiPAP may help with sleep apnea or related pulmonary insufficiency (82,130). Aggressive treatment of all upper respiratory infections in adults with OI is recommended (131). Asthma and chronic bronchitis may contribute to impaired pulmonary function and should be treated with bronchodilators, inhaled corticosteroids, and antibiotics when appropriate.

### Cardiac

A small number of adults with OI seem to have valvular problems. The most common is mitral valve prolapse. Dilation of the aorta also may occur but is rare. High blood pressure is as

common among adults with OI as in the rest of the population (131). High cholesterol and related lipid disorders that may occur in families can contribute to cardiovascular disease. Medical management of these disorders includes appropriate diet and drug therapies and regular monitoring by a primary-care doctor. Drugs such as statins can be very helpful along with diet in controlling lipid problems. Coronary artery surgery has been successfully performed on people with OI, although precautions are necessary because of tissue fragility.

### Hearing

Approximately 50% of all adults with OI will experience some degree of hearing loss during their lifetime (130). Hearing tests and MRI examination of the hearing canals can help delineate the involvement of the bones of the ear. Treatment for hearing loss usually begins with hearing aids. Some adults are candidates for either stapedectomy or cochlear implant surgery.

### Vision

The connective tissue problem in OI can extend to the eyes. Eye examinations are recommended every 2 to 3 years. OI can affect the shape of the lens and the strength of the sclera (131). For this reason, adults with OI should consult with an ophthalmologist before using contact lenses. Also, laser lens surgery is not recommended for people with OI.

### Gastrointestinal

Gastric problems are not uncommon in OI. These include gastric acid reflux, which is aggravated by a decreased length of the chest cavity, and chronic constipation. Short stature and frequent use of various pain medications can contribute to the problem. Constipation symptoms should be treated aggressively.

### Basilar Impression

Also known as *basilar invagination*, this is a special problem for adults with Types III and IV OI. Basilar impression (BI) involves pressure from the spinal column on the base of the skull. Symptoms can include headache, muscle weakness, and tingling or numbness of hands and feet (130). Evaluation by a neurologist, including MRI examination of the cervical spine and base of the skull, is necessary. This condition may be progressive with age.

## ACHONDROPLASIA

### Background

Skeletal dysplasias are a group of genetic disorders resulting in short stature. Achondroplasia is the most common and affects approximately 1/15,000 to 1/25,000 live births. It is an autosomal dominant disorder but 75% of cases represent new mutations. Achondroplasia is caused by a mutation in the gene that codes for the fibroblast growth factor type 3 (FGFR3), which is located on chromosome 4. The average adult

height is approximately 4 ft for women and men (137). Intelligence is usually normal. Life expectancy for achondroplasia is approximately 10 years less than that for the general population (138).

### Problem-Based Approach to Management Cardiac

It has been found that mortality related to cardiovascular disease is increased more than ten times that of the general population and that males have a higher risk (138). Cardiovascular-related deaths were increased twofold, but associated heart disease risk factors were not significantly increased (138). Screening for cardiovascular risk factors is, therefore, an important part of health maintenance.

### Nutrition

Obesity is a significant health problem in achondroplasia and has a prevalence of 13% to 43%. It begins in early childhood and occurs at all ages (139). Maintaining an appropriate weight is important given that obesity is a preventable risk factor for cardiovascular disease.

### Musculoskeletal/Neurological

Musculoskeletal complaints are prevalent in adults with achondroplasia. In one study, almost 50% of those over 20 reported leg pain and 70% of those over 50 reported back pain (140). Deaths from a neurologic cause were increased eightfold and occurred at all ages in a 42-year follow-up study, including sudden death in infants and children from foramen magnum stenosis (138). Lumbar spinal stenosis with neurologic compromise is a common complication in achondroplasia and one third will require surgery. It does not typically develop prior to age 15 and is often associated with increased kyphosis (141). Symptoms include weakness, pain, numbness, and bladder incontinence. Surgical decompression is required if conservative management fails. Postural kyphosis is a common occurrence in children but usually disappears with onset of walking. It may persist into adulthood in more than 10% of persons as a result of structural wedging of the vertebra (142). Posterior spinal osteotomy with instrumentation in those with neurologic deficits has shown to be successful in this population (143).

### Women's Issues

Fertility is usually not affected. Women with achondroplasia may have an increased risk of uterine fibroids, therefore, oral contraceptives should not be used long term. All women require caesarian delivery due to small pelvic outlet. Spinal anesthesia is not recommended due to possible spinal stenosis. Premature menopause has been reported (144).

### Quality of Life

Persons with short stature can experience many social and emotional challenges in an "average-sized world." Adults with achondroplasia tend to report lower QoL and self-esteem levels (145). Little People of America has played a significant role by providing a network in which information can be shared and support provided to those with skeletal dysplasias.

## CONCLUSION

Adults with childhood-onset disabling conditions are generally healthy and can be expected to lead meaningful, active lives. Not all adults have serious health problems, and many now recognize the aging process as a natural course of events, as it in the general population. The most common age-related changes and secondary conditions involve physical performance and the musculoskeletal system. Prevention strategies require anticipation of potential secondary conditions, communication of risk, recognition of changes that alter function and require intervention, and an understanding of interventions that have an impact on function. This requires that adults with childhood-onset disabling conditions have access to knowledgeable health care providers, and the medical systems necessary to implement a medical home approach to management of chronic illness and disease. Environmental, communication, attitudinal, and systems barriers must be overcome.

It is time to reconsider the model of illness and disease for persons with lifelong disabilities. Particularly in the realm of mobility, a health and wellness model should be developed. Use of prevention strategies must be considered in childhood and adolescence to address the more frequent secondary conditions. Programs of fitness and exercise have been proven beneficial in nondisabled groups and disability groups alike. Health promotion strategies should be employed for adults with childhood-onset disabling conditions. The inclusion of preventative measures into the model of chronic disease management will further solidify the team approach implied in the medical home concept and ensure that this population receives the high-quality health care that every person deserves.

# Empowering Women with Disabilities to be Self-Determining in their Health Care

## INTRODUCTION

In increasing numbers, women with disabilities are finding their way into public offices, educational institutions, health care organizations, corporate boardrooms, science laboratories, the arts, and sports arenas. They are defying the old adages of “can’t do” and invisibility and becoming authors and sculptors of their lives. With wisdom and resilience born out of years of hardship, exclusion, and prejudice, women with disabilities are finding their voices and increasingly shaping the world. They are declaring that no longer is it shameful to inhabit a body that is atypical in its anatomy or physiology or to need personal assistance services (PAS) (1). They are challenging us to question the wisdom of the drive toward homogeneity and independence with counter images and enhanced notions of diversity and interdependence as integral girders to the society of the future.

Nowhere are those voices more loudly heard than in the health care setting. Without question, in the last 20 years many social barriers have eroded. Curb cuts, accessible transportation and communication systems, and greater access to public spaces including higher education and the work place are increasingly expected “norms” in the community. Ironically, health care, a critical resource in the lives of many people with disabilities, has been one of the slowest domains to change and adapt (2–5). But the pressure is on. Women with disabilities are no longer accepting second-class health care, tolerant of a denied mammogram or Pap smear because they cannot stand or get onto the examination table. No longer are they willing to endure exclusion from reproductive health care services, based upon the mythology that they, as disabled women, are asexual, childlike, and unlikely interested or able to become wives and mothers (Fig. 58-1).

This chapter is intended as a resource to help health care professionals (HCP) work in partnership with women with disabilities to meet these gender specific needs (6). We have chosen to organize the chapter around topics that affect all women with disabilities regardless of age or stage of life as well as those that are specific to particular stages of growth and development. These topics include access to health care and preventive care including breast health and cervical cancer screening, menstruation and reproductive health care issues for the adolescent girl and young adult, issues of identity

and self-esteem, contraception, pregnancy, parenting issues including custody and adoption, menopause and aging with a disability, mental health, and domestic violence and abuse. Osteoporosis and sexuality, though critical topics for disabled women’s health care, are not discussed, as these topics are covered in other chapters (Chapters 39 and 51 respectively). The chapter is organized loosely around the different broad life stages, with a focus on both reproductive and psychosocial issues. Our topics represent issues that women from the disability community have told us are important to them, from their writings, conferences, research, and their collaboration with health care providers (7,8). This chapter is meant to highlight principles that will enable women with disabilities and their HCPs to advocate for the quality of care that they, as women, need.

In this chapter, the phrases “women with disabilities” and “disabled women” are both used. Language is constantly evolving and in disability communities, “... a controversy has raged over preferred linguistic usage” (9). The term “people with disabilities” underscores “the importance of the individual in society and disability as being something *not* inherent in the person” (9). The term “disabled people” emphasizes minority group status and pride in disability identity. Consistent with this emphasis on disability as a social minority identity and not only a medically defined deficiency, the authors of this chapter have chosen to use these terms interchangeably.

## BARRIERS TO HEALTH CARE

People with disabilities are no strangers to barriers (Table 58-1). The most overt barriers are physical such as stairs, narrow doorways, curbs, and inaccessible bathrooms (6,10–12). Another type of physical barrier is inaccessible medical equipment, such as examination tables, bariatric scales, and mammogram machines. Communication barriers include lack of sign language interpreters, materials in Braille, large print, or on computer disk. Programmatic barriers encompass lack of trained physical assistance, inflexible scheduling, and transportation difficulties. Economic barriers also play a significant role in preventing people with disabilities from accessing community services, such as health care (13). The most insidious barriers, however, are erected by ignorance and negative social attitudes

**FIGURE 58-1.** Mother with disability with daughter.

about life with disability (9). Women with disabilities, in particular, are disproportionately affected by discriminatory practices in employment, education, vocational services, economic programs, access to benefits and services, health care, and parenting activities (14,15). With the passage of civil rights laws such as the Americans with Disabilities Act (ADA) in 1990, and expanding clinical services targeting the needs of women with disabilities, this situation is beginning to improve (16,17). We are a long way, though, from full integration, where a woman with a disability can go to a community health center with the expectation that it will be fully accessible with wheelchair-adapted equipment and knowledgeable staff trained to assist women with a variety of disabilities in a manner respectful of their womanhood (Fig. 58-2).

The unequal representation of women in health care research is another barrier to health care facing women with disabilities (18,19). Historically, women have often been excluded from medical research for a variety of offered reasons ranging from methodologic issues about the menstrual cycle to liability concerns related to potential pregnancies (20). As a result, we have had little information about the causes and most effective treatment for major diseases of women such as coronary artery disease, the number one killer for both genders (21,22). The Women's Health Initiative of the National Institutes of

**FIGURE 58-2.** Disabled woman getting a mammogram.

Health, launched in 1991, was a major effort to address these deficiencies with a 15-year commitment of funding for large multicenter studies on topics such as breast and colon cancer, osteoporosis, and heart disease (23). Unfortunately, women with disabilities were not identified as a subpopulation for study; thus, despite the richness of the information, it did not help answer particular questions about the similarities or the distinctions of these health issues in the context of disability.

## DEMOGRAPHIC FACTORS

Based on the American Community Survey conducted by the U.S. Census Bureau in 2007, it is estimated that 15.5% of females over the age of 5 are disabled, 6.5% have one type of disability, and 9.0% have two or more types of disability (24). These figures are for civilians and noninstitutionalized persons. When considering the entire U.S. population, estimates are likely higher, with the most recent population-based data indicating that 21.3% of the female population has a disability, slightly higher than men (19.8%). They also tend to have more activity limitations than men with disabilities (25). Women with activity limitations are less likely to be married compared to other women and men with or without activity

**TABLE 58.1** Access Barriers

- Physical
  - Environmental
  - Equipment
- Communication
- Programmatic
- Financial
- Attitudinal

**TABLE 58.2** Employment and Poverty Comparison, American Community Survey, U.S. Census Bureau, 2007

Disability Status	% of Females Who Are not Employed	% of Females Who Are Below the Poverty Level
With no disability	30.7	12.2
With any disability	66.9	23.0
With a sensory disability	61.1	21.5
With a physical disability	70.5	22.3
With a mental disability	74.6	29.0
With a self-care disability	84.0	24.9
With a go-outside-home disability	84.6	24.2
With an employment disability	84.4	32.6

limitations. There is evidence that severity of disability plays a role. Only 44% of women with “severe” activity limitations (unable to carry on a major activity for their age group such as work, independent living, attending school, etc.) are married, and these women have higher rates of divorce than women with less severe limitations (26). About a third of women with disabilities have children at home, compared to about a quarter of men with disabilities (27).

In general, women’s education level is inversely related to degree of disability (25). Women with disabilities are more likely to live in poverty, be unemployed, or if they are employed make less than either women without disabilities or men (Table 58-2). Women with disabilities are as likely as nondisabled women to have health care coverage but are more likely to have publicly funded coverage (as opposed to private insurance) than nondisabled women (13).

## HEALTH DISPARITIES

The burgeoning literature on health disparities underscores that women with disabilities are subject not only to economic barriers but also to the lack of access to health care (2,5,28). The data on access is not straightforward, however. For example, in a recent analysis of a national probability sample (29), researchers examined health care access using eight measures including sources of care, insurance status, satisfaction, Papanicolaou test, and breast exam. They conclude that, “although the women with disabilities had similar or better potential health care access than nondisabled women, they generally had worse realized health care” (29). More specifically, women with disabilities were more likely to postpone care and medications and were less satisfied with their medical care than women without disabilities, although they had higher rates of a “usual source of health care.” In a longitudinal study of medical expenditure survey data (30), disabled women were less likely to receive Pap smears, mammography, and other cancer screening services but more likely to receive influenza immunization, and colorectal and cholesterol screening. Furthermore, there were significant socioeconomic and racial differences in access.

The authors conclude that disability is a barrier to preventive clinical services and “a key issue for improving women’s health care is to identify those who are at risk for specific measures of preventive care and also recognize subgroup disparities in care” (30).

These findings regarding health disparities in reproductive health care screening (e.g., Pap smears and mammograms) have been replicated by others including a study of women with major mobility impairments who were compared to their nondisabled counterparts (31). In addition, it appears that the severity of disability inversely correlates with the likelihood of receiving Pap smears and mammograms for women with physical disabilities (32). Furthermore, disparities for women with severe impairments appear to be exacerbated by a variety of factors including lack of knowledge on the part of health care providers, systems issues, ineffective communication, and lack of access to health information and services (33).

There is growing evidence of health disparities in the treatment phase of an illness and not just in health care screenings. In a retrospective observational study of women with stage I to IIIA breast cancer, those with disabilities were much less likely than other women to receive radiotherapy following breast conserving surgery than nondisabled women (34). Many reasons are posited for such disparities, ranging from absent or inadequate health insurance, patient preferences, lack of physical access or transportation resources, and attitudinal bias. Further research is needed to uncover the causes for these health disparities.

## REPRODUCTIVE HEALTH CARE

Women with disabilities overwhelmingly report difficulties obtaining balanced information about reproductive health care issues, techniques for managing menstruation, birth control, risks associated with pregnancy, techniques for labor and delivery, information about sexual functioning, dating, gender identity, etc. (1,35,36). Consistent with the rehabilitation model, it is our recommendation that the physiatrist works with a team of HCPs, including obstetrician/gynecologists,

urologists, anesthesiologists, and allied health professionals, who are committed to delivering knowledgeable, respectful, and accessible reproductive health care services to women with disabilities. What follows are some general suggestions and tips to help optimize the access to needed reproductive and preventive health services for women with disabilities.

### **Preventive Health Care Services: Pap Smears and Gynecologic Examinations**

Basic preventive health and gynecologic screening for women with disabilities is often overshadowed by more obvious physical or neurological problems, which may require more immediate focus (37). Thus, screening for diabetes, hypertension, hyperlipidemia, and thyroid imbalance, all of which are common concerns for women, may be neglected in women with disabilities. Many women avoid gynecologic care because of difficulty in obtaining an accessible, comfortable, and dignified examination (1,36,38). As a consequence, treatable early-stage problems may escalate and become much more difficult to manage. These concerns include Pap smear screening as well as breast evaluation.

Performance of the pelvic examination must be tailored to a woman's physical impairments often through the use of creative positioning techniques (39,40). An accessible examination table that lowers to wheelchair height and has security features such as hand rails, boots, and straps can be indispensable (39). Leg adjustments should be performed slowly and gradually to minimize pain and spasticity. Liberal application of lidocaine gel to the perineal area can be helpful in minimizing spasticity or in preventing episodes of autonomic hyperreflexia (AH) in some spinal cord injured women with high lesions (above T6) (41).

### **Preventive Health Care Services: Breast Self-Exam and Mammograms**

As of 2004, breast cancer afflicted 126.4 per 100,000 women/year, making it the most prevalent gynecologic cancer occurring in women (42). Currently, it is estimated that one in eight women will develop breast cancer. As a screening tool, mammography detects 80% to 90% of breast cancers. While there is general agreement that all women of age 50 and older should have yearly screening mammograms, there is still no clear consensus regarding women between the ages of 40 and 49 (43). Women with disabilities should, at the very least, obtain screening mammography at rates comparable to nondisabled peers.

Unfortunately, many facilities utilize equipment unable to easily accommodate mobility-impaired women. Though universal design mammography equipment is available, not all mammography centers or technicians are knowledgeable about how to accommodate women with disabilities. There are ongoing efforts to educate breast health providers about how to ensure that women with disabilities are accommodated (44–46). Women with disabilities should ask their health care provider for the names of facilities in their area best able to accommodate their disability and should contact the center in

advance to notify them of any special needs they might have. Although many authorities dispute the value of the breast self-exam and have muted prior calls for its monthly performance (47), many women informally check their breasts after their menses or at a regular interval in order to report any concerning changes (48). Women with disabilities, particularly those lacking manual sensation or dexterity, might need to rely on a partner or personal attendant to assist with this examination.

## **REPRODUCTIVE AND HEALTH ISSUES FOR ADOLESCENT GIRLS AND YOUNG ADULTS**

### **Management of Menstruation**

Menarche is a symbolic moment in most women's lives, marking the transition from "girlhood" to "womanhood," with the attendant procreative possibilities. For young girls growing up with their disabilities, it can also bring a host of stresses—from the practicalities of managing menstrual hygiene to the parental anxieties and concerns raised by menstruation (49–52). Parental discomfort can encompass a wide range of issues: the need to assist with menstrual hygiene; concerns about menstrual cramps and painful periods (particularly for those daughters with intellectual or communicative disabilities); maturation and secondary sexual characteristics of their daughters with awareness of vulnerabilities for sexual abuse; interest in dating and sexuality; and potential pregnancy. The recent Ashley X case, which involved a novel growth attenuation treatment for a young girl with "static encephalopathy," also raised the issue of the parental concerns about their daughter's future care, particularly as they contemplated the maturation of her body from a lightweight young girl easily portable by family members to an adult woman's body (50–52). The report of the growth attenuation treatment sparked much controversy about whether a treatment should be offered to both surgically and hormonally alter the body of children with developmental disabilities in order to make their care easier (with the belief that such an action will improve the person's quality of life) (50). A number of disability activists and organizations have subsequently come out with strong statements against the practice (53–55).

When HCPs are faced with parental requests for sterilization or hysterectomy as a means of managing their minor child's menstrual hygiene or concerns about future pregnancy, it is helpful to have some resources and guidelines. In general, the indications for hysterectomy and sterilization should be the same as for the nondisabled population, and other less invasive interventions should be considered to address the identified problem. The American College of Obstetrics and Gynecology Committee have issued an opinion on "Sterilization of Women, including Those with Mental Disabilities" (56), and present guidelines for consideration of these requests for both women with capacity to consent and those with cognitive disabilities who are not able to provide adequate informed consent. Given the permanency of the procedures and the possibility of coercion and abuses, many

states require that the courts be involved if a decision is made to proceed with sterilization of a minor child or woman with cognitive disability. Though the hysterectomy in the case of Ashley X was not done with the primary intent of sterilization, the case was investigated by Washington Protection and Advocacy (57). In their report, Washington Protection and Advocacy laid out some ground rules for future decision making around similar cases which included

- Need to get a court order/permission before doing a sterilization procedure or growth attenuation treatment in a minor child with disability
- Need to have a disability advocate involved in ethics decision making around such cases

Though the ruling is applicable to the state of Washington only, it is important to know the laws in the particular state of residency regarding sterilization procedures of minor children or disabled adults who lack decision-making capacity.

When possible, HCPs need to proactively address these issues with both girls growing up with disabilities and their parents, introducing options for managing menstrual flow if possible, before the onset of menstruation (58–61); such discussions offer opportunities for girls with disabilities to develop a sense of control over their emerging sexuality and evolving images of themselves as women. For parents of girls with disabilities, the discussions offer opportunities to address their fears and concerns with balanced information, creative options, and the perspectives of the lived experience of women who grew up with their disabilities.

For women with acquired disabilities who are still menstruating, management of menstrual flow should be addressed shortly after the onset of disability, preferably as a part of a rehabilitation program. Some women may be able to work with a nurse or occupational therapist to develop a system for managing menstrual hygiene. Other women may find that switching to sanitary pads if they had previously used tampons may be all that is needed. Still other women may elect to work with a personal assistant to manage their menstrual hygiene. Some women, particularly those with more extensive physical disabilities, may find these options impractical and choose to look for pharmacological options (i.e., hormonal interventions) to regulate or curtail the menstrual flow (62–67). While there are a number of options used by women in general, there is little data on the safety and usage of these treatments in women with disabilities. Unfortunately, some physical disabilities and chronic disease states are inherently associated with menstrual irregularities, leading exactly to the unpredictable flow that is so unwelcome.

### Access to Information

It is estimated that girls with disabilities (age 21 and younger) comprise 8% of female youth (25). While girls and young women with disabilities share similar health care issues with their nondisabled peers, their health encounters are likely to be more frequent, intense, and complex (68). In addition to routine adolescent health needs, disabled girls may encounter

a regime of disability-specific repeated hospitalizations, health visits, and medication schedules that can intrude into their family, school, and social lives. Sensitivity to the medicalization of these girls' lives is important and should be demonstrated by actively engaging the girls in the decision-making process as it affects their health issues. This can be accomplished in partnership with a parent or caregiver as long as the girl is not coerced into unwanted decisions and supported with information in a user-friendly format that allows her to be self-determining. The promotion of self-determination in girls and young women with disabilities serves to decrease the incidence of negative health encounters while optimizing the likelihood of compliance with healthy life choices.

Lack of access to information can prevent girls and women with disabilities from achieving self-determination in health and other aspects of life. Research suggests that “adolescents with disabilities are likely to be participating in sexual relationships without adequate knowledge and skills to keep them healthy, safe, and satisfied,” and are twice as likely to experience sexual abuse (69). Their exclusion from sources of information about sexuality and reproductive health options has been assisted by inadequate disability accommodations, negative disability attitudes, or a combination of both types of barriers (70). Many girls with disabilities grow up outside the usual channels for learning about sexuality. For example, they may be denied admission to their neighborhood schools and recreation programs due to access barriers and discriminatory enrollment practices (71). Consequently, they are denied important informal opportunities to exchange information and experiences regarding sexuality with their peers. Instead, they might be placed in a sheltered and closely supervised “special education” school where even formal sex education may not be offered. Their parents are less likely to talk to them about sexuality and reproduction than to their nondisabled sisters (68). Girls and young women who are blind are rarely given tactile anatomical models so they can safely explore and understand the form and function of human body parts. Those who are deaf or hard of hearing may miss conversations about “the facts of life” whispered between hearing friends. Girls and women with cognitive disabilities may not fully understand spoken and written information about sexuality and health matters unless it is presented in an illustrated, uncomplicated manner. There are some materials that are helpful in preparing girls and women with disabilities for their first pelvic and breast exams, such as the video and workbook “Let’s Talk About Health: What Every Woman Should Know” designed for girls with developmental disabilities (72).

In adulthood, information barriers interfere with health maintenance for women with disabilities (6,11). Blind women and those with low vision confront clinic signs, instructions, release forms, and educational materials that have not been translated into accessible formats, such as Braille, audio-tape, or computer disk versions. Deaf women are not offered interpreters to insure accurate doctor/patient communication. Women with cognitive disabilities are not allowed adequate time and explanation to ensure comprehension and informed

consent. There is also evidence that physicians' perceptions of a woman's disability may result in the withholding of information about her health options. One of the first systematic studies to document disabled women's health service experiences (38) revealed that physicians' inclination to offer disabled women patients information regarding sexuality and contraception was mediated by such factors as the age of onset and extent of a woman's disability.

Some reproductive health agencies, such as Planned Parenthood and Regional Family Planning, have taken important steps to ensure that their information and services are accessible to women with disabilities. State or city government offices specializing in disability services can guide physicians in providing accessible information and communication to patients with disabilities. A useful rule of thumb in working clinically with any woman with a disability, particularly early onset disability, is to ask if she would like information or guidance about sexuality, reproductive health options, or any other aspect of health. Some women with disabilities are sophisticated about their health options and the workings of their bodies; others lack basic information about anatomy and human sexuality. Many are experts regarding their particular disability but have gaps in general health maintenance knowledge due to the information barriers discussed above. It is important to explore with each woman her level of knowledge and desire for more information before concluding any health service contact.

### Personality/Self-Esteem

Girls and women with disabilities are as tremendously diverse as any other category of human being. Indeed, the development of personality characteristics and life histories will influence a woman's reaction to medical intervention, her adjustment to changes in functioning, and her coping mechanisms. In this section, we will begin by briefly reviewing personality factors—the relatively stable dispositional and relatively malleable situational variables that impact human functioning. For rehabilitation professionals, however, the research literature on experiences of marginalization, disempowerment, self-esteem, and implicit messages about what it means to be a woman with a disability are important to consider. After a general discussion of personality and self-esteem, we will summarize some research literature focused specifically on women with disabilities.

Personality psychology is a diverse area of study. McAdams and Pals (73) outline five big principles in personality theory and research: evolution and human nature, dispositional traits, characteristic adaptations, life narratives, and culture. Evolution has impacted human nature, resulting in fundamental ways in which human beings are the same. Specifically, there are some universal, cross-cultural, and historical aspects of human life which have evolved over time such as adaptation and cooperation. Sheldon (74) focused on three psychological needs: “need to sustain a basic sense of self (autonomy), to manipulate the environment in order to achieve instrumental goals (competence), and to form cooperative relationships with others (relatedness)” (73). For women with disabilities,

the issues of autonomy (or self-determination), competence, and relatedness are as fundamental to their flourishing as they are for health care providers and family members who each bring their own perspectives to the medical encounter.

The second principle is the importance of dispositional traits. Dispositional traits include what has classically been referred to as the big five factors of personality: openness, conscientiousness, extraversion, agreeableness, and neuroticism (75,76). Debates within personality psychology have focused on dispositions versus situations, but there is some consensus that there are broad dimensions of human personality that account for consistency over time and differing contexts. It is these deep-seated dispositional traits that underscore the variation within women with disabilities. The third principle is characteristic adaptations. These include goals, strategies, values, schemas, and “many other aspects of human individuality that speak to motivational, social-cognitive, and developmental concerns” (73). The fourth principle is life narratives, or the life stories that individuals construct, retell, and constantly recreate to make sense of their world.

In the past several decades, research into narrative identity has opened up new ways of thinking about the self. These narratives open up room for change and also for making sense of disparate experiences, or for reframing negative experiences into more positive ones. Beyond the narrative identity that is constructed through stories that give meaning to our lives, women with disabilities have various identities that may impact their adaptation to impairments. For some women, a disability identity that focuses on pride and social structures will be prominent. For other women, ethnic identity, such as “Asian American,” may be an important way to reframe stories. For individuals who face “oppressive narratives about their social identities,” (77) alternative stories may increase their resilience to these negative narratives.

Finally, the fifth principle of an integrative science of personality is the differential role of culture. Culture can impact some aspects of our personality (e.g., narrative identity) while others may be less amenable to change (e.g., neuroticism). Furthermore, different cultures may encourage certain behaviors or ways of thinking about the world. For example, an American woman with a disability may focus on individual rights, while a South Asian woman with a disability may focus on social roles. The general discussion of personality highlights the opportunities for health care providers to tailor their health care provision with these factors in mind.

### Self-Esteem and Self-Determination

The concept of self-esteem has the qualities of a personality trait and a psychological state (78) and refers to an appraisal of one's worth. Other terms such as self-regard and self-respect have also been used in the literature. Recently, scholars have focused on specific aspects of self-esteem. For example, Crocker et al. have defined “contingencies of self-worth” or domains from which individuals derive their perception of self-worth. They describe the domains of virtue, God's love, support of family, academic competence, physical attractiveness, gaining others'

approval, and outdoing others in competition (78). Therefore, self-esteem is contingent on the extent that an individual bases her self-worth on a specific domain, and either succeeds or fails in that domain.

The majority of the research on self-esteem has focused on the level of self-esteem, high or low, and the assumption has been that high self-esteem is associated with positive outcomes. Recently, researchers have suggested that the relationship may be weaker than previously assumed (79). Crocker and Park (80) further argue that “the pursuit of self-esteem interferes with relatedness, learning, autonomy, self-regulation, and mental and physical health. Pursuing self-esteem can be motivating, but other sources of motivation, such as goals that are good for the self and others, can provide the same motivation without the costs” (80).

When the HCP focuses on perceptions of self-esteem, he or she may be limiting the creative solutions to goal attainment. For example, if a woman reports low self-esteem and views this as a global construct about her worth, and the HCP is complicit in this belief, alternatives may not be suggested. Focusing on specific activities, on areas of strength, on relationships and interdependence, rather than individualistic perceptions of self-worth, may provide alternative ways of positive adaptation.

In a study focused specifically on the self-esteem of women with physical disabilities, Nosek et al. (81) assert that it is not the disability itself but the contextual, social, and emotional impact that affect the women’s sense of self. The authors state, “we learned that their self-evaluation was strongly influenced by feedback from parents and other family members, teachers and schoolmates, friends and intimate partners. The impact of this feedback about their value as women with disabilities was predominantly negative” (81). The authors also discussed the importance of activities and the various barriers, environmental and attitudinal, that negatively impacted the women. In their study comparing 475 community-dwelling women with disabilities to 406 women without disabilities, they found that women with disabilities had significantly lower self-cognition, self-esteem, quality of intimate relationships, employment, and less education. They had higher social isolation and overprotection during childhood. The authors further state, “The social environment in which women with disabilities live is primarily a hostile one, transmitting stereotypes that have existed for millennia, resulting in stigmatization and exclusion” (81).

Some young women with disabilities, however, including those with extensive physical limitations, have demonstrated resilience in the face of invalidating messages. They have developed positive self-concepts as women and have established enduring intimate relationships despite all predictions (8). Many give credit to perceptive family members who affirmed their gender roles and who facilitated their social contacts. Others, surrounded by discouragement, refused to internalize it. Seeking strong disabled women role models for support or simply finding validation from within, they have integrated their disabilities into sound and positive identities as women (68,71). Accepting disability as a familiar and “normal” part

of their lives, they seem to set their own standards for what is valuable, sexually appealing, and womanly.

Self-efficacy, or one’s beliefs about her capabilities to attain goals, is also related to the construct of self-esteem. In a qualitative study of women and men that examined the perceptions of self-efficacy and rehabilitation with patients with traumatic brain injury (TBI) and stroke (82), the authors identified 11 themes that patients described as helping them engage effectively in rehabilitation. In the first domain, *self*, the first five themes were self-reliance, determination, independence, recognizing own improvements, and pushing one’s limits. In the second domain, *others*, the next three themes were external reassurance, vicarious experience, and working with professionals. In the third domain, *process*, the final three themes were setting goals, information needs, and making time for rehabilitation. The authors suggest that examining self-efficacy is one way to “maximize the benefit gained from rehabilitation” (82). In the outpatient setting as well, focusing on task mastery and use of vicarious experiences (e.g., peer support) may be an effective means for increasing self-efficacy and psychosocial outcomes.

Self-determination is also influenced by self-esteem. Self-determination is distinct from independence, in that someone can be physically dependent on others but be self-determining in their choices and preferences. In the psychological literature, Self-Determination Theory (SDT) (83) refers to a theory of human motivation that encompasses the concepts of perceived competence, autonomy, and relatedness. More specifically, SDT differentiates between autonomous and controlled motivations. “Autonomous regulation involves experiencing a sense of choice, a sense of full volition,” whereas controlled regulation “involves people feeling pressured or controlled by an interpersonal or intrapsychic force” (84). Autonomous motivation leads to lasting changes and positive behaviors while controlled regulation results in temporary changes. For women with disabilities, as with any other patient, HCPs have an important role to play. For example, HCPs can provide relevant feedback to encourage mastery and work toward a strong sense of relatedness which involves trusts and connection. This can lead to higher self-determination and willingness on the part of the patient to learn and adopt new strategies for health improvement (84). In general, when physicians support the concepts of self-determination in their practice, there are positive outcomes such as adherence to medications and improved physical and psychological health (85).

## REPRODUCTIVE AND HEALTH ISSUES FOR WOMEN OF CHILDBEARING AGE

### Menstrual Irregularity and Fertility in Women with Physical Disabilities

Women with disabilities need to be empowered to not only understand their bodies and how they work but also to direct their choices regarding reproductive health care. For some women, this may involve decisions regarding childbearing.

For most women with physical disabilities, fertility potential is preserved, and menses resemble the patterns of women without disabilities (86). In some cases, though, menstrual irregularity and fertility problems can occur. The most common hormonal imbalances found in women in general are disorders of prolactin secretion or thyroid function. Disorders of neuroendocrine function are not uncommon after TBI, though there is no clear data on the frequency with which it affects the menstrual cycle or fertility (87). In an analysis of 13 pooled studies with 809 people with TBI, the prevalence of hypopituitarism in patients at least 5 months post TBI was found to be 27.5%; with a greater prevalence found in populations with more severe injuries (88). Some groups now recommend routine screening for hypopituitarism of patients with moderate to severe TBI (88,89).

For women with spinal cord injury (SCI), almost all women will resume their normal cycle within the first 3 to 6 months post injury (90); about 25% of one population of women studied report increased autonomic symptoms (sweating, headaches, flushing, gooseflesh) around the menses (91). Occasionally, medications can also cause menstrual irregularities. Phenytoin and corticosteroids may affect thyroid function and ovulation; tricyclic antidepressants, antipsychotic medications, and some antihypertensive medications may also cause menstrual irregularities by affecting prolactin levels (86,92,93). Treatment of menstrual irregularities varies with age and medical condition. Pregnancy should always be considered in evaluating menstrual irregularity. Thyroid function tests and prolactin levels can be helpful in evaluating women with irregular menstrual periods (94,95). Correcting hormonal causes of menstrual irregularities can often regulate the menstrual cycle successfully and improve fertility. In short, for women who desire to conceive and are having difficulties, they need to undergo an evaluation identical to those without disabilities (96). The male partner needs to be involved in the process by providing a semen specimen for analysis, as about 40% of all couples who present with infertility problems will have a male factor contribution (96).

Abnormal bleeding can also occur with structural problems such as uterine or endocervical polyps, fibroids, cervical pathology, and vulvovaginal lesions (97). Menstrual irregularities become more common as women approach menopause. Careful gynecologic evaluation is required to determine an appropriate course of treatment. Although gynecologists frequently prescribe low dose combination oral contraceptives and other hormonal agents either to regulate menstrual flow or control vasomotor symptoms, there is no data derived from studies of women with disabilities to guide practitioners (62–67).

## Contraception

The history of contraception for women with disabilities has at times been coercive and even frankly oppressive. Dating back to the early 1900s, fears of women with disabilities producing children with disabilities led to some social policies encouraging sterilization and criminalization of marriage (98,99). Other fears have checkered the reproductive history of

disabled women, including the perceived inability of women with disabilities to be “good” mothers and exaggeration of health risks for women with disabilities who choose to bear children (100–102). Concerns about “physician-controlled” contraceptives, such as Depo-Provera (Upjohn, Kalamazoo, Michigan), still percolate in segments of the disability community as a result of this history and the fear that a woman’s reproductive choices might be curtailed by physicians, parents, or guardians who make decisions on her behalf (103,104). Sensitivity to this history is essential in establishing patient-centered, trusting relationships between health care providers and women with disabilities. Women with disabilities have the same right to knowledgeable information about contraception as nondisabled women and should participate in their reproductive health care decision to the fullest extent possible. Contraceptive choices may be colored, though, by the nature of the woman’s physical impairment or chronic disease condition (105). For example, a woman with impaired hand function may have difficulty using barrier methods such as the diaphragm, sponge, or spermicidal product without assistance. Problem solving with an occupational therapist, or working with the woman’s partner or personal assistant, may result in an adequate solution for the use of barrier methods. Condoms, of course, always remain an effective method if the male partner is in agreement and provide the dual benefits of contraception and protection from sexually transmitted diseases (106).

There are a rapidly growing array of hormonal options for contraception that include a variety of combination pills, progestin-only mini-pills (62), injections (e.g., Depo-Provera—depot medroxyprogesterone acetate), subdermal implants such as Implanon (Schering Plough, Kenilworth, New Jersey), transvaginal rings, such as Nuvaring (Schering Plough, Kenilworth, New Jersey), the levonorgestrel intrauterine system (Mirena; Berlex Laboratories, Inc., USA), and transdermal patches such as OrthoEvra (Ortho-McNeil Pharmaceutical, USA). For women who desire hormonal methods of contraception, information about the risks and benefits of various hormonal contraceptive options in women with disabilities is limited. For example, some women with mobility limitations (such as women with spina bifida, SCI, and multiple sclerosis [MS]) might have an increased risk for developing thrombotic events when using combination oral contraceptives, but definitive statistics are not available (105). Women with a history of thrombotic or thromboembolic stroke should probably avoid estrogen-containing contraceptives (105). There is some indication that there may be a protective effect between oral contraceptives and rheumatoid arthritis, but the results thus far are inconclusive (105). The progestin-only contraceptive pills are associated with an increased risk of abnormal uterine bleeding and are less effective than the combination pills (62). Depo-Provera, an injectable form of progesterone that is effective for at least 12 weeks, is highly effective, and patients are often pleased with the decreased menstrual flow or amenorrhea that results from this method (107,108). Many women experience some weight gain and have reduced estrogen levels, which can lead to osteopenia (109). Indeed, Cromer et al. (110)

documented a 3% loss in bone mineral density among adolescent girls who should typically have experienced a 9% increase in bone mineral density. Concerns regarding how prolonged use of Depo-Provera might impact peak bone mineral density and subsequent risk for osteoporosis later in life prompted Food and Drug Administration (FDA) to issue a “black box warning” in 2004 (111). For women with disabilities who often confront an elevated risk of both osteopenia and osteoporosis due to chronic immobilization, this consideration is particularly important and providers should use caution when prescribing this for more prolonged periods of time.

Implanon (Schering Plough, Kenilworth, New Jersey), an etonogestrel containing subdermal implant, has been available worldwide since 1998 and in the United States since 2006. Unlike Norplant, a six-rod levonogestrel implant previously available in the United States, Implanon consists of only one 4 cm, plastic rod implanted at the biceps-triceps junction of the nondominant arm. Placement consists of a minor procedure that resembles receiving an injection. Removal is far less problematic than encountered with Norplant. Approximately 10% of women discontinue Implanon due to irregular bleeding and many other patients note occasional breakthrough bleeding (112). This might present a hygiene issue for women with chronic immobility impairments. Limited data are available to assess pharmacokinetic changes among Implanon users taking other medications that induce hepatic microsomal enzymes. Although pregnancy associated with Implanon is rare, several pregnancies reported with its use occurred in women using carbamazepine or other enzyme-inducing agents (113). Fortunately, the implant exerts little impact on bone mineral density and contains no estrogen.

OrthoEvra is a transdermal patch applied weekly on the buttocks, abdomen, upper torso, or outer arm. Approved in the United States in 2002, OrthoEvra offered a novel method of delivering hormones, contained in combination oral contraceptives, for patients unable to swallow a pill or who could not remember to take a daily pill. FDA issued “updated labeling” in 2005 following reports of venous thromboembolism (VTE) associated with its use (114). Risk of VTE typically correlates with estrogen dose, and 3 weeks’ of patch use exposes patients to roughly 71% more estrogen (“area under the curve”) than ingestion of a low-dose oral contraceptive (115). Although the absolute risk of VTE remains small among users, patients at elevated risk of VTE, including chronically immobilized patients, should likely forego its use until more data becomes available.

Nuvaring is a flexible, transparent ring placed in the vagina 3 out of 4 weeks/month. Indications and contraindications to the ring resemble traditional oral contraception. Unlike the OrthoEvra Patch, Nuvaring exposes women to less estrogenic exposure than either the patch or pills while providing superior cycle control (115). Women with disabilities might find it difficult to check for the ring’s presence in the vagina, particularly after intercourse when the vagina physiologically dilates and may need the assistance of their partners to do so. Women with denervation atrophy and relaxation of the pelvic floor

might also have difficulty retaining the ring and approximately 5% of women discontinue the ring due to “ring-related” issues such as vaginal discharge.

Intrauterine devices (IUD) represent the most popular form of reversible contraception throughout much of the world but remain underutilized within the United States. Despite contraceptive efficacy that approaches that of surgical sterilization, many clinicians still fear infectious and other risks previously attributed primarily to shield type IUDs (116). Recently, clinicians in the United States have begun to rethink an unjustified bias against intrauterine contraception, liberalizing prescribing practices to include groups such as nulliparous patients and adolescents (117). No literature specifically evaluates the risk of IUD use among women with disabilities, though physicians should clearly exercise caution in some circumstances. Women with impaired pelvic sensation, for example, might be less able to detect symptoms consistent with pelvic infection as well as spontaneous expulsion of the IUD. Other women will have difficulty palpating vaginally for the IUD string, one sign that the IUD remains properly placed, and again may require the assistance of their partners or personal assistants to do so. Although the FDA has not approved IUDs for noncontraceptive indications, progestin-bearing IUDs may offer the opportunity to control menometrorrhagia without resorting to more invasive, surgical methods (116). This might offer significant hygienic advantage to women with mobility impairments who experience heavy or irregular menses—regardless of their need for contraception.

### Pregnancy and Prenatal Preparation

When possible, as with any nondisabled woman, it is best to discuss issues and concerns about pregnancy and motherhood *before* becoming pregnant (6,118,119). Preconception counseling allows the woman to carefully consider any disability-specific factors which may raise medical concerns or issues for the woman, her partner, and her health care team to consider. Counseling about health behaviors such as diet, potential adverse effects of smoking, alcohol and illicit drug use on the fetus, and the benefits of various vitamin supplementations (such as folic acid), all may maximize the woman’s ability (disabled or not) to make choices and be an active participant in managing her pregnancy (120).

As many women with disabilities are on multiple medications, such as antiepileptic and antispasticity agents, careful consideration of the potential effects of the medications on a developing fetus is warranted (121–125). Although many physicians continue to rely on FDA’s Use-in-Pregnancy Ratings when prescribing medications during pregnancy, organizations such as the Teratology Society (Teratology.org) have recommended abandoning use of this system, since it fails to realistically balance the likelihood of fetal risk against maternal benefit (126). The benefits, for example, that many disabled patients derive from antiepileptic, antispasmodic, and other medications might justify some fetal risk in order to assure that the patient avoids seizures, worsening immobilization or other maternal compromise that unduly jeopardizes the health of both mother

and baby. Obstetricians enrolling disabled prenatal patients can now utilize numerous web-based resources, particularly regional and state teratogen information services, to obtain current data regarding fetal risk. As the intrathecal baclofen pump becomes an increasingly common tool for managing severe spasticity, it is inevitable that more disabled women who become pregnant are likely to have a pump. Though there is limited experience with the use of the pump in pregnancy, labor, and delivery, the information thus far has been reassuring for both mother and fetus/baby (127–130).

For some women, information about their health risks with pregnancy may be useful in facilitating a decision to pursue biological motherhood. A few disabilities may progress with pregnancy or in the postpartum phase, perhaps irreversibly, or require higher-risk interventions and support (131–139). For example, a woman with multiple sclerosis may expect that her MS could worsen postpartum though pregnancy itself does not seem to have a significant long-term impact on disease course (140–144). Similarly, a woman with spinal muscular atrophy may need ventilatory assistance as the gravid uterus pushes up on her diaphragm and impedes ventilatory excursion (134,138,145–147). Women with spina bifida, particularly those with shunts for hydrocephalus, urinary diversions, kyphoscoliosis, contractures, and pelvic obliquity may be at increased risk for pyelonephritis, shunt malfunctions, and caesarian sections (139). Pregnancy for patients with systemic lupus erythematosus (SLE) may pose health risks for both the mother and the fetus, though the prognosis has improved with better understanding of the pathogenesis of the disease and improved treatment options (148).

Women with physical disabilities may experience a temporary decrement in their functional abilities as pregnancy progresses, necessitating more physical assistance or different mobility devices (91,149,150). Most women with mobility impairments will be affected to some degree by changes in their center of gravity with increasing weight gain. Women who had previously managed their mobility with braces or assistive devices may find their stamina and balance affected as the pregnancy progresses and elect to temporarily use a manual wheelchair (150). Women who had previously been independent with manual wheelchairs may notice that they fatigue much more quickly and are unable to navigate the environment independently; these women may choose to use a power wheelchair in the latter stages of pregnancy. Some of these women will also appreciate the option of using a power mobility device postpartum to transport their child. Anticipating these changes will allow the woman and her health care provider to determine needs that might arise during the pregnancy and plan proactive interventions (such as referrals to physical therapy in the second trimester) that can be instituted to lessen the impact of some of these changes (150).

Information about other potential risks associated with pregnancy may assist in developing a plan of care to obviate or lessen these risks (106,121,134,139). For example, for women who use indwelling catheters and are chronically colonized with bacteria, the risk of bladder infections and pyelonephritis

may be heightened (91,151–153). Prompt recognition and prevention of urinary tract infections is extremely important in preventing preterm labor (152). Women who have been accustomed to intermittent catheterization may find their bladder capacitance decrease, with increased leakage or frank incontinence, particularly during the latter stages of pregnancy. Increasingly, urinary diversion is being offered as a means to manage the neurogenic bladder for people with physical disabilities (154–157). This population poses particular considerations in the managements of pregnancy, labor, and delivery, especially if a caesarian section is required.

Another potential complication of pregnancy for a woman with mobility impairment is skin breakdown. Excellent skin care and vigilance are extremely important in preventing pressure ulcers during pregnancy for any woman with areas of insensate skin (121,150). A pressure-relief program that had previously been adequate in preventing pressure sores may no longer be adequate with the increasing weight gain and hormonal changes of pregnancy. Counseling about more frequent pressure reliefs, evaluating the adequacy of the wheelchair cushion, and increasing the frequency of skin checks are good prevention strategies. Counseling with the labor and delivery staff about padding and positioning is also crucial in preventing this complication.

Constipation and hemorrhoids are potential problems in any pregnancy with changes in diet, hormonal influences on the intestinal tract, iron supplementation, and the gravid uterus pushing on pelvic veins, but these potential complications can be particularly difficult for a woman with a neurogenic bowel dysfunction who must use a bowel program (158). Vigilance, modifications in diet and the bowel program, and proactive bowel hygiene can go a long way in preventing potential bowel impaction and hemorrhoidal complications.

Pregnancy is a time of hypercoagulability for all women, and may pose increased risk for deep venous thrombosis for women with mobility impairments (106,159). Frequent examinations and counseling about signs and symptoms of deep vein thrombosis (DVT) are extremely important in helping women and care providers quickly recognize and seek assistance in managing this potentially life-threatening complication. Counseling regarding periodic elevation of the legs, watching the salt intake, and the use of compression stockings may help minimize dependent edema.

For women with respiratory impairments from SCI, neuromuscular disorders such as spinal muscular atrophy, or extensive scoliosis with restrictive lung disease, respiratory function may also be affected with lowering of the functional residual capacity as the uterus grows (106,121,160). Pregnant women frequently hyperventilate and develop a mild degree of respiratory alkalosis, believed to be an effect of progesterone (160). Women with limited respiratory reserve may be particularly affected by these changes and require some modification in their activities, sleeping positions, and occasionally, ventilatory assistance to manage the later stages of pregnancy, labor, and delivery (138). There have even been reported cases of women who had no autonomous ability to breathe on their

own and successfully used noninvasive ventilation throughout pregnancy (161).

A few potential complications of pregnancy can be life-threatening for a woman with disability (162–165). One of the best recognized and frequently written-about complications is AH in a woman with tetraplegia or high paraplegia (usually T6 or above) (121,163–167). Not only can AH signal an issue requiring immediate attention such as bladder distention or infection, bowel impaction, or labor, but also the signs and symptoms can be misinterpreted as preeclampsia and lead health care providers down an incorrect path of diagnosis and treatment. Untreated AH can result in intracerebral hemorrhage and even death. For women who are at risk for AH, consultation with an anesthesiologist well before delivery may be prudent (162–165,168). A team approach to pregnancy, with a specialist in SCI working closely with the obstetric staff, can facilitate prevention and management of these potential complications (35,106,121). Women with disabilities other than SCI also benefit from consultation with an anesthesiologist prior to labor and delivery, including women with lung and cardiac disease, skeletal abnormalities and scoliosis, and MS (169).

Pregnancy offers an excellent opportunity for the woman with disability to begin to prepare for her future role as a mother (150,170,171). If a woman has an extensive mobility impairment, referrals to an experienced occupational therapist and physical therapist may help her to develop a variety of anticipated skills to maximize her ability to parent (150,172–175). For example, how will she carry the baby? How will she feed the baby? If she plans to breast-feed, what positioning techniques will work best for her? What about diapering, dressing, and bathing? A home visit may be helpful in setting up the environment with adaptive equipment to facilitate her functional abilities. If the woman will require or chooses to use assistance in managing some of the baby care tasks required, working out a plan prior to delivery is important.

Many women with disabilities also yearn to talk to other women with similar disabilities about their experiences as mothers. Peer support and referrals can be extremely helpful in facilitating successful adjustment for both mother and baby and in anticipating the needs of each subsequent developmental stage (150,176). If a woman uses a wheelchair, how will she manage her toddler and maintain safety and discipline? How will she work with her child around the child's growing perception of her disability (177–180)? Women also report that continued contact with child care specialists from occupational therapy and psychology can be extremely important in adapting to each new developmental stage. More detailed information and resources on mothering with a disability are presented later in the chapter.

### **Labor and Delivery**

Preparation for labor and delivery is an important consideration for the woman with a disability, though, depending on her disability, the traditional childbirth classes may not be adequate for her and her partner (150). Information to assist the

woman in proper recognition of labor involves understanding expected signs and symptoms in the context of her particular disability (121,181). For example, a woman with extensive sensory impairments may not be able to sense pain from uterine contractions but have to rely on manual or electronic detection of the contractions. If she has high paraplegia or tetraplegia, periodic headaches from recurring AH (occurring with each contraction of the uterus) may be the first symptom she recognizes. It is important that the pregnant woman be instructed on the early signs of labor, including recognition of amniotic fluid leakage, and know when to seek immediate care. Of course, frequent regular checkups with her obstetrician will also be helpful in predicting impending labor.

As previously mentioned, a discussion of anesthesia before labor and delivery is important in establishing a care plan (162,163). For example, consideration of an epidural catheter may be important for a woman at risk for AH (e.g., not to manage pain but to block the afferent signal from the uterus to the spinal cord triggering the sympathetic response (121,162,165)). For a woman with respiratory compromise, a plan for providing ventilatory support should be discussed if this becomes necessary. If general anesthesia is needed for any reason, pertinent knowledge about disability-related issues that could influence the safety of general anesthesia should be considered. For example, a woman with a SCI should not receive succinylcholine as a depolarizing agent secondary to the risk of hyperkalemia (162,182). In addition, if a woman has had a cervical fusion of her neck, oral intubation may be difficult.

Working with the labor and delivery staff is also be important in anticipating the needs of a woman with disability. If she is at risk for skin breakdown, proper padding and frequent position changes are important. If she has significant contractures and spasticity, tips for managing these issues with range of motion, positioning, and occasionally, medication may be advisable (150). An increasing number of women are being recognized with latex allergies, in particular a large proportion of women with spina bifida (183), and this should always be mentioned to the staff as well. It is optimal if the woman (and her partner) has an opportunity to tour the facility where she will deliver, to have an opportunity to ask questions about accessibility (e.g., bathrooms, showers, etc.), and to discuss her wishes for her peripartum care with her obstetrician and the nursing staff.

## **MOTHERING WITH A DISABILITY**

A growing number of women with disabilities are choosing to become mothers, defying stereotypes of asexuality and maternal incompetency historically ascribed to them by a society that stigmatizes disability (Fig. 58-3). They and mothers who later acquired disabilities are seeking recognition and support for their capabilities. This surge was generated in the 1970s by the independent living movement and in the 1990s by the passage of the ADA and is forcing health care providers to take a closer look at ways to assist mothers with disabilities to

**FIGURE 58-3.** Mother with disability and her daughter.

achieve self-determination over their parenting activities. Best estimates suggest that of the 6.9 million disabled parents in the United States, approximately 60% are women, and about a third of these women, compared to 25% of disabled men, have children in the home (27).

Although mothers with disabilities share the same basic needs and concerns as nondisabled mothers, their capabilities to function aptly in a parenting role are greatly enhanced with the use of adaptive equipment and techniques. Also vital is having regular access to peer support, and knowledgeable health care providers who understand the concept of self-determination, as well as the sociopolitical barriers confronting women with disabilities (184,185).

Mothers with disabilities have more possibilities for support and resources available to them than ever before, for example, through the Internet, specialized resource centers, and rehabilitation specialists. Yet, many women with disabilities live in fear of their children being taken away from them if they do not live up to other people's expectations, and thus feel they have to go to great lengths to present themselves and their children as managing "normally" in order to be accepted as "ordinary" mothers (186). This is a realistic fear, as historically the lay public and HCPs have questioned the capacity of women with disabilities to be care providers, based upon the perception and presumption that those who receive care (e.g., PAS) could not then provide care to others (186). Findings from a national study of parents with disabilities confirm the prevalence of discrimination that mothers with disabilities face

regarding their rights to bear and raise children (27,187–190). Of the more than 1,000 parents with physical, sensory, and/or cognitive disabilities surveyed, 15% reported that others attempted to remove their children (27).

## Research

While research on disabled parents is relatively scarce, some significant strides have been made in the past 25 years, spurred by the dedicated work of a national center. In 1982, Through the Looking Glass (TLG) was founded in Berkeley, California, as a disability community-based organization, a product of the independent living movement. It is dedicated "to create, demonstrate, and encourage nonpathological and empowering resources and model early intervention services for families with disability issues in parent or child which integrate expertise derived from personal disability experience and disability culture" (191). In 1998, TLG became the first National Center on Parents with Disabilities, funded by the National Institute of Disability and Rehabilitation Research, U.S. Department of Education. In addition to performing research, TLG provides information, referral, publications, training, and consultations regarding parenting with a disability (including counsel on custody, adoption, and adaptive baby care equipment). The research is conducted from a disability cultural perspective, an approach grounded in the view that disability does not reside solely within the mother, but rather is socially constructed in her experiences of discrimination and marginalization.

TLG remains on the forefront of conducting research that documents the capabilities of mothers with disabilities in an effort to combat pervasive stereotypes that emphasize the negative effects of a mother's disability on the well-being of her children. Its early research was driven by data showing that parents with physical, visual, and hearing disabilities "were offended that professionals had questioned their abilities to care for their babies, implying that the parents had never considered the baby care implications of their own disabilities" (188). From 1985 to 1988, TLG explored basic infant care tasks including feeding, lifting, bathing, diapering, and dressing by videotaping the interactions between ten mothers and their infants (192). They were able to capture the gradual process for mutual adaptation that emerged between mother and baby during their interaction (192). For example, the study documented the process of reciprocal cooperation between a mother with paraplegia and her 1-month-old infant who would help his mother lift him by balling up his legs and head on his mother's lap and remaining still until his mother completed the lift. The videotape documented the mother's cuing process that facilitated the infant's adaptation through a series of strategies that included positioning the baby on his back and a variety of tugs on his clothing that signaled her intention to lift him. Also, mothers with hemiplegia report that their children knew at an early age to always approach their mothers on their stronger side and to refrain from extending arms to be picked up when their mothers were standing or not in a more stable, seated position (192). This study offered practitioners an expanded working sense of range of "good enough

parenting” to include issues of physical difference in mothers (188). The findings demonstrated that mothers with physical disabilities were naturally resourceful in creating their own adaptations to baby care and that adaptation in infants was often easily facilitated by their disabled mothers.

TLG’s videotape evaluation and analysis methods can be an invaluable tool for clinicians and health providers called upon to assist parents with disabilities involved with child protective services systems (188). In one renown incident that involved Tiffany Callo, a mother with cerebral palsy who lost her two sons to foster care, the TLG video based analysis was able to demonstrate that Callo’s diapering skills were within the range of “good enough” (188). Furthermore, when Callo’s lack of a mutual gaze with her infant was interpreted by social service professionals to be pathological, TLG researchers directly challenged this assessment with the introduction of a lap tray and well-positioned pillows that allowed Callo to establish a mutual gaze with her infant, which she was previously unable to achieve when left solely to her own abilities. TLG determined that Ms. Callo’s experience and that of many others underscored the necessity for ensuring the provision of adaptive baby equipment when attempting an accurate assessment of a disabled woman’s full range of mothering abilities. This is especially important in situations that involve a disabled woman’s legal rights as a parent or in custody decisions.

TLG continues to spearhead research that helps improve the quality of family life for individuals parenting with a disability. Three important initiatives conducted by TLG that are of particular importance to rehabilitation clinicians include (a) the development and evaluation of babycare equipment, (b) a national survey of parents with disabilities, and (c) a study examining the effects of mothers with disabilities on their children.

### Research Initiative on Babycare Equipment

TLG has undertaken some pioneering work in babycare equipment including the design and evaluation of lifting harnesses for use by mothers with physical disabilities (193–197). By lessening the disabled mother’s level of physical stress and fatigue, these studies demonstrated that the provision of adaptive equipment and adaptive techniques can help prevent secondary disabilities such as back or repetitive stress injuries. In addition, the equipment was found to help with “alleviating depression associated with postnatal exacerbations of disability such as in MS” (188).

Although accessible babycare equipment is more commercially available now than ever before, it can be difficult to find accessible cribs and playpens. Some equipment needs to be customized to be truly accessible, which can pose liability issues. It can also be difficult to find skilled and affordable rehabilitation engineers to make the necessary adaptations. Sometimes, creativity and nontraditional equipment can be used (198). Irrespective of whether a mother is seeking to locate commercial baby equipment or equipment customized by rehabilitation engineers or fabricating the adaptations herself with tips from parenting groups on the Internet, it is

essential that all equipment be safe for use by both the mother and child, which can be determined by the evaluation of a skilled occupational therapist.

### Research Initiative on National Parenting Survey

In the largest national study of its kind (27), 1,175 parents with disabilities were surveyed on their needs and experiences that included the barriers they encounter in their role as parents. Noteworthy are findings that reveal that parents with disabilities face significant social barriers that impede their parenting activities such as the lack of accessible transportation (87%) and lack of accessible housing (69%). Fifty percent of respondents also reported they did not know how to locate adaptive parenting equipment, but a predominance of respondents felt their independence, efficiency, stress, and fatigue would improve if it were available. Forty-eight percent reported difficulties in affording adaptive equipment, even if it were available.

### Research Initiative on the Impact of a Mother’s Disability on her Family

Research on the predictors of problem parenting were the same as those for nondisabled mothers (e.g., history of physical, sexual, or substance abuse in the mother’s family of origin) (188) and challenge the common stereotype that children of mothers with disabilities will be “parentified” or obliged to care for the emotional or physical needs of their disabled mothers at too early of an age (188). In fact, contrary to being parentified, this study found that children of disabled mothers were often spared the responsibilities of common family chores, such as taking out the garbage, when the mothers felt that the request was in any manner “necessitated” by their disabilities (188). An additional study by other researchers who looked at mothers with SCI found that there were no significant differences between children raised by mothers with SCI and children raised by mothers without disabilities in regards to individual adjustment, attitudes toward their parents, self-esteem, gender roles, and family functioning (180). It is commonly reported that among the multitude of positives that disabled parents offer their children are the ability to learn compassion and an openness toward others.

### Facilitating Self-Determination

Although the introduction of adaptive equipment and parenting resources early in the mothering experience can minimize problems and significantly improve a disabled mother’s capacity to provide “totally independent care” for her baby, this is not feasible for all mothers. Financial constraints, difficulty finding people who can fabricate equipment, scarcity of customized equipment, and physical limitations may still prevent many women from becoming fully self-sufficient in managing the care of a child. In fact, over half (57%) of disabled parents report that they used personal assistance for help with parenting tasks (27). It is thus essential for mothers and health care providers alike to recognize that a disabled woman’s lack of physical independence does not necessarily diminish her mothering skill. Rather, it shifts the focus to the value of

facilitating self-determination instead of self-sufficiency in the parenting role. This distinction is a crucial one.

A caregiver can be a family member, spouse, friend, or hired personal assistant. Caregivers are most beneficial when they enhance the special bond between a parent and child (199). Health professionals and occupational therapists can help maximize the value of hired caregivers by facilitating childcare training to teach the caregiver how to assist the disabled mother without taking over the role of the parent (175). It is also important to help the mother find her role during the activity. For example, as the caregiver diapers the baby, the mother can engage the baby in play activities.

Recently, TLG devised an assessment tool, Baby Care Assessment for Parents with Physical Limitations or Disabilities, administered by an occupational therapist that is used to evaluate a disabled mother's full range of parenting capabilities (200) (Fig. 58-4). The tool emerged from the disability community and incorporates perspectives of parents in this community. For instance, independent performance is only valued as much as the parent needs or desires it. The tool brings together the parent's experience, including a self-assessment, and the evaluation of such factors as cognition, ergonomics, environmental barriers, and mental health issues, and

then analyzes how those aspects effect the child care activity. It includes tips and questions that guide assessment and a screening of parent/child relationship issues as well as appropriate referrals. It has also been used successfully, as one aspect of evaluation, in mandatory assessment situations involving family court or child protection systems. An alternative instrument, though less comprehensive than the TLG tool, can also be used as a screening tool for mothering tasks (Fig. 58-5). On the basis of the assessment, the occupational therapist, mother and spouse, or caregiver collaborate to determine the tasks the disabled mother needs simplified, is comfortable performing independently, or will delegate to helpers.

The lack of disability-aware social institutions and services can pose real threats to the self-determination of mothers with disabilities. Not uncommonly, states exclude child care from the list of activities of daily living for which a disabled person can get personal assistant support. Unfortunately, women with disabilities who have a low income and are unable to afford private child care have lost custody of their children because the state refused them assistant services and then deemed them incompetent in parental functioning (100). Full knowledge of relevant state policies on the provisions of personal assistants will create realistic expectations on the part of prospective

(From *Baby Care Assessment for Parents with Physical Limitations or Disabilities: An Occupational Therapy Evaluation* (2005). Tulejcia C, Rogers J, Kirshbaum M & Abrams K. Through the Looking Glass, Berkeley, CA.)

Item Name: Care of Others (Child Care)

Definitions:

- a. **Physical daily care**--Selects proper equipment, uses correct positioning, and performs the following:
  - Feeding--breastfeeding, bottle feeding (includes set-up and clean-up), spoon feeding (includes opening jars)
  - Changing a diaper--donning and removal (specify type: cloth with pins or diaper cover or plastic with tape) and managing hygiene
  - Dressing/undressing--Donning and removal (specify type: one-piece jumpsuit, t-shirt, plastic pants, dress with snaps or buttons, socks, shoes, booties)
  - Bathing--Holding, washing, drying off (indicate location: tub, sink, positioning device)
  - Preparing for bed--Changing clothes, lifting and lowering side of crib, moving child from crib to lap or wheelchair, covering child with blanket
  - Carrying/lifting--Lifting to and from floor and transporting 50 feet
- b. **Playing/nurturing**--Selects appropriate toys/activities, uses age-appropriate interaction, and is aware of various intervention strategies for behavior management and facilitation emotional growth
- c. **Illness/first aid**--Takes temperature, uses nasal aspirator, manages suppositories, and gives medication. Is aware of symptoms and is able to perform minor emergency procedures (cuts choking, CPR, poisoning), "baby-proofing" of home, and seeking assist in an emergency
- d. **Community access/resourcing**--is able to select and access day care/preschool, child supplies, physician, babysitter. Is able to instruct babysitter. Is able to manage stroller and car seat (includes placement and removal from car, placing child in/out of devices), diaper bag, back pack.

Note: Select and note activities appropriate to the patient's lifestyle/abilities.

#### SCALE POINTS

NO CAREGIVER REQUIREMENT:

7. Complete independence: Patient can perform task safely and consistently within a functional amount of time in any environment without specialized equipment, modifications, or verbal/physical assist.
6. Modified independence: Patient can perform task safely and consistently without caregiver assistance but requires specialized equipment, an adapted environment, and/or excessive time to complete task.

REQUIRES CAREGIVER ASSISTANCE

5. Set-up/infrequent assistance: Patient consistently requires caregiver presence to initiate and/or complete task (e.g., with set-up and/or clean-up), but patient safely and consistently completes interim components independently, or patient requires caregiver's assistance for unpredictable occurrences only.
4. Minimal assistance: Patient performs more than three quarters of the task safely and consistently. Because of physical or cognitive impairment, patient requires caregiver to provide physical or verbal assist to complete one quarter of the task.
3. Moderate assistance: Patient performs half to three quarters of the task safely and consistently. Because of physical or cognitive impairment, patient requires caregiver to provide physical or verbal assist to complete on quarter to half the task.
2. Maximal assistance: Patient performs one quarter to half of the task safely and consistently, or may be physically unable to perform any part of the activity but can accurately direct the caregiver. Patient requires caregiver to provide physical or verbal assist to complete the remainder of the task.
1. Dependent: Patient performs less than one quarter of the task consistently. Patient is unable to direct the caregiver and is dependent of the caregiver's physical or verbal assistance for completing more than three quarters of the task.

**FIGURE 58-5.** RIC functional assessment scale. parents and better aid practitioners in educating their clients and peers about ways to reduce the risk for unnecessary removal of children from their disabled parents.

### Child Protective Services: Empowering Mothers With Disabilities and Their Advocates in Court

Despite the increase in parenting resources and the fact that there is no scientific evidence for a correlation between a parent having a disability and inadequate parenting, mothers with disabilities can encounter discrimination in the legal process and find themselves in circumstances where their right to parent is unfairly challenged

(201). Such legal challenges require that disabled mothers defend their parental right to the companionship, control, and custody of their child (201). When the state threatens to remove a child from his or her mother, the situation can be frightening and complex for the entire family. It can involve documentation and testimony from rehabilitation clinicians who need to be prepared to challenge the misconception that women with disabilities, by virtue of their disability, should not have children and are unable to care for them. When preparing to advocate on behalf of a mother's parental right, it is critical that the advocate understands the rules specific to their state or county that determine the state's definition of "unfit" (201) (Fig. 58-6).

**FIGURE 58-6.** General guidelines for assessing parental fitness.**A FIT PARENT**

- ❖ Meets the **Physical Needs** of the child
- ❖ Meets the **Emotional Needs** of the child
- ❖ Preserves the **Health and Safety** of the child

**Source:** Callow, E *Child Protective Services/Dependency Court Experience: Guide for Parents with Disabilities and Their Advocates* Berkeley: Through the Looking Glass 2008

All advocates or mothers with disabilities who have questions or concerns about parental rights for mothers with disabilities are encouraged to contact the National Resource Center for Parents with Disabilities to help determine state specific rules and the procedures involved regarding the procurement of an attorney or preparations for a Dependency Court experience (1-800-644-2666). In some states, once clear and convincing evidence has proven a parent unfit, the state must yet also prove to the court that it is in the best interest of the child for the parent's rights to be terminated. The age and sex of the child, mental and physical health of the parents, emotional ties between the parents and the child, as well as the parent's ability to provide the child with food, shelter, clothing, and medical care are among the many factors that may be considered by some courts in determining the best interest of the child (201).

Certainly, a goal of all rehabilitation clinicians working with prospective or current mothers with disabilities should be to help assess the mother's ability to adequately parent with the supports of appropriate baby equipment, parenting techniques, and social support as mentioned above, but also to offer guidance on local resources to help the parents negotiate the challenges of creating a child-centered home that improves their child's well-being, and is appropriate for the developmental stages. Disability-savvy social workers, psychologists, and pediatricians, in addition to physiatrists, physical therapists and occupational therapists, and peer support are all potential resources that can assist a new mother with disability to develop her parenting capacities. When possible, the earlier the process of parenting evaluation and support can be initiated, the better. A skilled occupational therapist can help the mother identify commercially available, safe adaptive baby care equipment, learn childcare techniques, and create a plan for how to make the home safely accessible and childproof (193,197). It is important that women develop a plan for how any childcare needs will be met, if an assistant will be required, and to have the opportunity to network with other mothers and learn about social and community resources. Continued contact is important as the child grows and develops to anticipate the future needs of the child (150).

## Adoption

Stereotypes depicting women with disabilities as having to be "cared for" rather than as caregivers present ongoing challenges to those women wishing to adopt children (202). Given the lack of a universal standard for good parenting, agency staff may impose arbitrary standards onto disabled individuals applying for adoptive services (203). Despite these disincentives, many disabled men and women are taking advantage of the advocacy

services of disability service groups and the supports of knowledgeable physicians and health providers to successfully negotiate the social and attitudinal obstacles to become adoptive parents (204). When screening for the parenting capabilities of a prospective parent, it is not uncommon for an adoption agency to require a physician's certification documenting the individual's good health and ability to raise a child (27). Before rendering a determination, rehabilitation and medical practitioners should carefully consider the prospective parent's support network and full spectrum of parenting abilities. To focus on the disability as a negative to the exclusion of a woman's full range of beneficial attributes may result in the denial of a child's placement with a caring and competent parent. Disabled women report that an unfavorable medical determination adds to the frustrations of an already stressful adoption process and can reinforce a host of self-doubts and low self-esteem (205). In one case a physician, familiar to a disabled couple, surmised that their cerebral palsy represented a potential hazard to raising a child. The mother later on documented the couple's challenges and successes in becoming adoptive parents by engaging in a national writing and speaking campaign to enlighten disabled women and their service providers on strategies for maximizing adoption options (202). Among the suggestions that she offers medical professionals who can often make or break a couple's chances for adoption (205) are the following:

- Read the literature on adoption for people with disabilities available via the TLG Web site [www.lookingglass.org](http://www.lookingglass.org).
- Remember that the same screening standards should be applied in adoption screening of all potential parents, whether they have a disability or not.
- Learn about the disabled parent's support system, what resources are available to them, that is, family, friends, neighbors, and childcare assistance?
- Examine your own concerns and be honest about your discomfort. Consider whether you are the best person to handle this issue.

When a clinician is asked to be involved in evaluating parental rights in the legal process, it is important that the clinician attempts to obtain an evaluation of the prospective mother's parenting capacities and need for adaptations and supports (by an occupational therapist using an assessment tool such as those referenced above). If a judge refuses to finalize an adoption or a caseworker declines a consent to the adoption and the prospective adoptive parent believes these refusals are a result of discrimination, she may consider filing an appeal of the decisions or grievances with the adoption agency, state bar

association or in the case of judge based discrimination, with the Department of Justice (203).

### Peer Support for Parenting

Facing the onslaught of negative messages concerning one's reproductive and parenting capacities can reinforce self-doubts in even the most confident of disabled women. Advocates and experts around the world are finding that disability consciousness and culture emerging from the power of peer-to-peer contact are the tried-and-true remedy for counteracting the isolation and devaluation women experience when parenting with a disability (184,185). From each other, many women are hearing for the first time that their decision to become mothers is a valid one, a cause for celebration. They rely on one another for a wholeness and strength that come not from independence and self-sufficiency but from interdependence and self-determination. As disabled mothers increase in number, so are the national and international parenting networks for people with disabilities, many of them online. Most independent living centers can assist health providers in identifying the peer support groups and networks for disabled mothers and women in their area (<http://www.ilusa.com/links/ilcenters.htm>).

## MENOPAUSE AND AGING WITH A DISABILITY

More than half of women with disabilities in this country are greater than the age of 50 and pose unique issues in preventive health care services (206,207). Menopause is the permanent cessation of menses that occurs after the cessation of ovarian function and is frequently preceded by oligoovulatory bleeding. Menopause usually occurs in women between 45 and 55 years of age, with a mean age of 51, and is suspected after 6 months of amenorrhea. The diagnosis can be confirmed by findings of low estradiol and high follicle-stimulating hormone (FSH). These tests can be performed if the diagnosis is in question. The age of onset of menopause can occur earlier in women with chronic disease states such as thyroid disease, diabetes, and in diseases such as MS (208,209). Symptomatology may also vary in its manifestation and effects on women with disabilities. For example, women with neurologic conditions that are particularly heat sensitive, such as MS, may have difficulty distinguishing hot flashes and vasomotor instability of menopause from symptoms commonly attributed to their disability (210).

Women with physical disabilities may be at higher risk than their nondisabled counterparts for the consequences of estrogen deprivation such as osteoporosis or difficulties with skin integrity. For example, a woman with weakness or paralysis from a neurological disability may have extensive immobilization osteoporosis that occurred around the onset of the disability (211,212). She is still at risk for age-related and menopause-related bone loss but will be entering these phases with a lower bone mass to begin with. If she is at increased risk for pressure sores from immobility or loss of sensation, she may note increasing difficulty with maintenance of her skin

integrity and turgor around the time of menopause with the loss of estrogen.

Many women begin experiencing menopausal symptoms, particularly vasomotor symptoms, before cessation of menses. Provided they have no other contraindications to its use, low-dose combination oral contraceptives often provide the dual benefit of cycle control and amelioration of hot flashes. Other noncontraceptive benefits, such as reduction in risk of ovarian carcinoma, endometrial carcinoma, and preservation of bone mass, prompt some women to continue them until menopause is confirmed by evaluating gonadotropin levels. Though hormone replacement therapy (HRT) has been believed to be a safe and effective agent for many postmenopausal women and has also been used in the hope of preventing cardiovascular disease, osteoporosis, and even cognitive decline, recent studies have questioned the wisdom of routine use. The Heart and Estrogen/Progestin Replacement Study Follow-up (HERS II) found that HRT was not effective in preventing coronary artery disease and in fact, increased the risk of biliary tract disease and VTE (213–215). The Women's Health Initiative (WHI) arm that evaluated estrogen plus progestin was stopped early, as this large randomized controlled trial found an increased incidence of coronary events, strokes, pulmonary emboli, and invasive breast cancer in those receiving the combination HRT versus those receiving placebo. Data from the estrogen-only arm of WHI demonstrated similar findings. The WHI study did indicate some potential benefit in those receiving combination HRT for a lower risk of colorectal cancer and hip fracture (216). Physicians no longer use HRT as primary preventive treatment of heart disease or osteoporosis, as many other more effective treatments are effective (215,217). Aspirin,  $\beta$ -blockers, angiotensin-converting enzyme inhibitors, statins, and other lipid lowering strategies are important agents to consider as preventive strategies for coronary heart disease and cerebral vascular disease (215). A number of agents, including bisphosphonates and raloxifene, are useful in preventing fractures in women with low bone mineral density. Patients experiencing acute symptoms related to estrogen deprivation, including vasomotor symptoms, should realize that relative risks of major cardiac events and invasive breast cancer were low and only demonstrable after 4 years of therapy in the WHI trial. Immediately following release of the WHI trial data, The American College of Obstetricians and Gynecologists (ACOG) formed a task force to review and revise previous recommendations regarding HRT. ACOG continues to recommend that hormone therapy be individualized and that it "can still play a role in the treatment of menopause, provided you use the medications for appropriate reasons and after weighing the benefits and risks" (218).

Similarly, the North American Menopause Society (NAMS) position statement stresses the importance of individualization of therapy noting that providers cannot assume that all benefits and risks of HRT apply equally to all populations, at all ages, and for all durations of use (219). Given the remarkable heterogeneity of disability and its clinical sequelae, the need to specially tailor hormone replacement is even greater than among women without disabilities.

## DEPRESSION

It has been well established that women are troubled by significant depression at a rate approximately twice that of men (220–222). Among the causes hypothesized to explain this disparity have been physiology, particularly hormones, social oppression including restricted choices and narrow standards for appearance and behavior, and socially imposed powerlessness. The National Institute of Mental Health Web site elaborates “...many women face the additional stresses of work and home responsibilities, caring for children and aging parents, abuse, poverty, and relationship strains. It remains unclear why some women faced with enormous challenges develop depression, while others with similar challenges do not” (223). The reverberating effects of undiagnosed and underdiagnosed emotional disorders are hard to estimate. Moreover, most depressive disorders are treatable and HCPs should be aware of the signs, symptoms, and range of treatments available.

It has also been established that women with disabilities experience depression at higher rates than women without disabilities (224). The high comorbidity of depression and anxiety (225) also makes it likely that a range of clinically significant emotional disorders differentially impact women with disabilities. The multiple minority status of women with disabilities can elevate their risk for stress and mental health problems (226). Nosek et al. (224) discuss the antecedents of depression in women with physical disabilities. Factors include socioeconomic disadvantage, functional limitations, health disparities and secondary conditions, health behaviors, violence, self-esteem, sexuality, stress, and environmental barriers. The complexities and pressures of daily living with a disability command a balancing act of finding transportation, making appointments, filling out forms, negotiating with service agencies, managing personal assistants, worrying about equipment breakdowns, and coping with discrimination. For women, who are more likely than men with disabilities to confront poverty and social isolation, the lack of adequate resources can compound the routine pressures of disability, leading to depression and feelings of hopelessness.

Furthermore, access to intervention such as psychotherapy can be limited for women with disabilities due to lack of health insurance coverage and lack of practitioners with disability knowledge. Women who live in rural areas may be particularly affected by under diagnosis and lack of treatment. In one study of rural centers for independent living in nine different states, the majority of the participants reported symptoms of moderate to severe depression, with almost one in five reporting suicidal thoughts (227). Moreover, 36.6% of the women in the sample had not received any treatment for depression in the 3 months prior, and nonwhite women were more likely to be untreated. The authors conclude that social factors impact the causes of and treatments for depression. “Mobility limitations and pain can have a severe negative effect on a woman’s ability to engage in social activity. Diminished social networks and increased social isolation can increase the risk of depression, abusive relationships, and illnesses” (227).

A survey study of women with disabilities in Canada found a significant association between suicide, depression, and abuse (228). Of 371 women with a variety of disabilities, over 60% had contemplated suicide and over 45% of the contemplators had attempted suicide at least once. Approximately half had experienced physical abuse or sexual abuse, and two-thirds had experienced emotional abuse. The more types of abuse a woman had experienced, the more likely she was to have considered suicide. Aside from abuse, the two factors mentioned most by the women as contributing to their suicidality were poverty and isolation.

Treatable depression in disabled women remains undiagnosed when health service providers incorrectly assume that depression is a natural concomitant of disability. While depression is an expected feature of the initial disability adjustment process, it should be noted and addressed with support, counseling, and other interventions appropriate to situational distress. Beyond the adjustment phase, depression in women with disabilities calls for a thorough exploration of specific causes (whether directly related to the woman’s disability or not) and a review of potentially effective interventions. Peer support can be a powerful adjunct to professional treatment.

Unfortunately, many women’s clinics and community mental health centers are inaccessible to women with disabilities due to physical, economic, and communication barriers. Residential treatment programs for substance abuse and psychiatric disorders commonly refuse to admit women who use equipment or need physical assistance with activities of daily living. Access is limited for those seeking sexual counseling, psychotherapy, and suicide intervention, from therapists who are adequately informed about the stressors and options resulting from the interaction of being a woman and being disabled. A concerned physician can be an important ally in a disabled woman’s journey through depression, from identification of the problem to support in surmounting the barriers to adequate mental health services. The management of depression is a critical facet of disabled women’s health care, and the consequences of failing to address it can be grave. Psychosocial support can also mitigate symptoms of depression. Physicians can help link their patients to community resources for peer support and opportunities for self-expression. Physicians can acquaint themselves with independent living centers, a national network comprising hundreds of centers run by people with disabilities to provide disability-related information, services, and advocacy to others with disabilities. Most cities have one or more such centers, and many offer peer support groups and domestic violence programs as well as information on housing, health services, transportation and in-home PAS. Additionally, in many cities, there are disability rights and consumer organizations that can be contacted for resources helpful to women with disabilities. State, county, and municipal government offices routinely have departments addressing the needs of citizens with disabilities. By contacting these organizations and programs, physicians and the women with disabilities they serve can inquire about local recreational, artistic, employment, and peer support programs that welcome women with disabilities and provide potential psychosocial resources.

## VIOLENCE AND ABUSE

Despite the increase in research and public health campaigns on domestic violence over the past decade, domestic violence remains a complex social problem that is frequently invisible to health providers and the public. It is a crime of power that utilizes fear to control a victim and is an everyday reality in the United States. Most critically, violence and abuse are issues that pose severe health problems to women with disabilities (229–232).

Seminal work by Sobsey (233) long ago demonstrated a dynamic that intrinsically linked violence to disability, both as an outcome and as a means for establishing societal perceptions of women's vulnerability. This association creates a cycle of disability and violence, begetting more disability and violence, that easily entraps but proves difficult for a woman to escape (233) (Fig. 58-7). Recent evidence remains conflicted, but many experts agree that women with disabilities experience twice the rate (or more) of all forms of abuse and violence compared to other women (229–232,234). In one in-depth qualitative study of 181 women, women with physical disabilities were more likely to experience intimate partner abuse if the women perceived themselves as more sexually unattractive than women with lesser impairments. Negative perceptions of low body and sexual self-esteem, coupled with the woman's desire to be partnered, increased a woman's vulnerability to getting into and staying in abusive relationships (231).

The Center for Research on Women with Disabilities (CROWD) at Baylor College of Medicine defines abuse and neglect for people with disabilities to include emotional, physical, and sexual abuse (Fig. 58-8). In a research study comparing women with disabilities to a sister or close friend, CROWD found that women with disabilities were more likely to experience abuse if they were younger, less physically mobile, more socially isolated, and experienced depression (235). These

### DEFINITIONS OF ABUSE AND NEGLECT FOR PEOPLE WITH DISABILITIES

- ❖ **Emotional abuse** can manifest in "behaviors such as emotional abandonment and rejection, or denial of disability."
- ❖ **Physical abuse** "includes physical restraint of confinement; withholding orthotic equipment, medications, transportation; or refusing to provide assistance with essential daily living needs such as dressing or getting out of bed."
- ❖ **Sexual abuse** "includes demanding or expecting sexual activity in return for help or taking advantage of a physical weakness and inaccessible environment to force sexual activity."

Source: Nosek M.A., Hughes R.B. *Violence Against Women with Physical Disabilities: Findings from studies conducted by the Center for Research on Women with Disabilities at Baylor College of Medicine 1992-2002*. Fact Sheet. Houston; Center for Research on Women with Disabilities at Baylor College of Medicine 2002

**FIGURE 58-8.** Definitions of abuse and neglect for people with disabilities.

findings are also echoed by research on abuse involving people with disabilities which found that female gender, people who were younger, unemployed and uncoupled, were at risk for abuse (229). The reliance upon others for personal assistance (236) poses additional risk and makes it harder for a woman to escape the situation. Removing adaptive equipment or withholding needed care may be one way the abuse is experienced in the context of these relationships.

Researchers from CROWD identified that women with disabilities were more likely than their nondisabled peers to experience abuse from a significantly greater number of perpetrators that included attendants and disability service/health providers. Other offenders included spouses, ex-spouses, family members, strangers, and dates. Secondly, the CROWD study found that women with disabilities were more likely to experience abuse for longer periods of time (235) than women without disabilities. Environmental and attitudinal barriers may play a critical role in accounting for significantly longer periods of abuse (235). These two findings were also affirmed in a qualitative study that investigated care-related abuse in women with SCI (231).

Women revealed that they often refused to confront abusive PAS providers because of fear of retribution and to avoid having to find a new provider (237). Other studies on PAS abuse conducted by the Center for Self-Determination at Oregon Health and Science University participants described several barriers to addressing abuse: "(a) difficulty recognizing it and having their experiences validated; (b) feelings of shame or embarrassment; (c) lack of PAS providers and emergency backup services; (d) fear of institutionalization or loss of their children if they reported the abuse; (e) lack of access to abuse services such as crisis services, support groups, and domestic violence shelters" (236). Findings from this study also indicated that women found professionals of little help in helping them in identifying or addressing PAS abuse, but indicated that they would welcome being asked about these experiences and being assisted to discover management options (236).

Probing deeper into the nuanced differences between the experiences of disabled victims of intimate partner abuse and

**FIGURE 58-7.** Mechanisms that contribute to the abuse and disability cycle. (From Sobsey D. *Violence and Abuse in the Lives of People with Disabilities: The End of Silent Acceptance?* Baltimore, MD: Paul H Brookes; 1994:47.)

other abused women, Copel (230) studied the varied forms of disability-specific abuse in conjunction with the stresses women with physical disabilities identified as triggers to the abuse episode, their responses to the abuse, and the aftereffects of the episode (Fig. 58-9). When the stress level in the home exceeds the perpetrator's ability to cope, the likelihood of abuse increases. Such factors which can contribute to the stress may include financial problems, complex health issues, shortage of resources, a breakdown in support systems, and the perception of unmet sexual and emotional needs of the perpetrator. In each of the 25 transcripts analyzed by Copel, the woman's disability was mentioned as a stressor, a burden blamed for the conflict. The study noted that as the male partner's stresses increased and his ability to cope decreased, his verbal abuse escalated, sometimes exploding into acts of physical violence. While the start and progression of the violent process was similar to the patterns of violence experienced by nondisabled women by their intimate partners, Copel found that unlike their nondisabled counterparts, women with disabilities experienced no separation, or honeymoon periods from the violence. Rather than a period of separation that was followed by remorse, apologies, contrition, or reconciliation, women with disabilities after the abusive episode, experienced separation but indifference and learned to take their cues from their abusive partners and act as if nothing happened. The women rationalized the violence and lack of remorse from their male partners by commenting that their disability made them "less than" or "different from" other women. The women often stated that the male abusers regarded them in derogatory or dehumanizing terms as "nothing but a disability" or "physically damaged," which decreased

the quality of the couple's life. The unexpected finding that the aftereffects of violence differ significantly between women with disabilities and nondisabled women, caused investigators to construct the "Proposed Model for Partner Abuse in Physically Disabled Women."

Copel also found that the women were generally unsuccessful in their ability to stop the conflict or in their desire to find peaceful solutions, and it was only after the violence escalated and culminated into crisis that they were able to establish a connection with a health care provider or other women to help them recognize and label the partner's behavior as abuse. It was the crisis that was the main link to the health professional. Up until this point, it was difficult for the women to understand how to empower themselves or extricate themselves from the abuse (230).

Implications of this research for rehabilitation providers, clinicians, and advanced nurse practitioners are profound and cannot be overstated. Providers need to be proactive in working with women with disabilities and their partners to help them connect to resources that can alleviate stressors. Having options for disability-sensitive, therapeutic and social support interventions, for example, such as support groups or counseling, may help reduce social isolation, enhance self-esteem, educate the woman about what constitutes abuse, and help her implement health boundaries in relationships. Of course, interventions to enhance the woman's self-reliance and self-efficacy, though skills training, assistive devices, etc., can be extremely helpful. It is also important to assist women in creating safety plans when working with home or family care providers, so a plan is in place in case it is ever needed.

Abuse Assessment Screen-Disability (AAS-D): Measuring frequency, type and perpetrator of abuse towards women with physical disabilities. *Journal of Women's Health and Gender-Based Medicine*, 10(9), 861–866.

**FIGURE 58-10.** CROWD Abuse Assessment Screen-Disability (AASD).

It is essential that providers routinely assess for abuse among women with disabilities, talking to them in private without the personal assistant or partner present, and help them recognize the various forms abuse can take. Yet, a survey conducted by CROWD found that less than 20% of rehabilitation providers screen for abuse and violence (235). Despite the low percentage of disability providers who screen for abuse, there is evidence revealing that disabled women would welcome providers asking these questions (236) and that asking abuse screening questions can increase the detection of violence and abuse from 0.8% to 7% (238). The Abuse Assessment Screen-Disability (AASD) screening tool developed by researchers at the CROWD (Fig. 58-10) is one excellent tool for screening women with disabilities for general and disability specific abuse.

Finally, providers and clinicians must distinguish the subtle differences between the exacerbations of the woman's health condition, or the effects of her disability, from evidence of abuse such as severe anxiety, panic attacks posttraumatic stress disorder, depression, etc. Since the passage of the

ADA, domestic violence shelters in some states have improved their services to victims with disabilities and have committed to implementing disability-specific abuse screening protocols and disability-specific safety plans (239). But continuing limitations regarding the shortage of disability-friendly resources such as accessible housing, battered women's shelters, transportation, quality personal care attendants, disability-aware law enforcement officers, and accessible courtrooms can cause women with disabilities who are victims of partner or caregiver abuse to feel revictimized and frustrated in their attempts to obtain help (236,240).

The Disabled Women's Network of Canada were among the first to determine that the abuse experiences of women with disabilities are often not reported to law officers because of their fear and dependency on the offender (241). Anecdotal evidence suggests that, like other abused women, those who are disabled often resist reporting their experiences of abuse because of denial, guilt, self-contempt, and fear of loss of financial security. However, some experts believe that disabled women are

often discouraged from disclosure because they are commonly regarded as less credible and easily discredited as witnesses by virtue of having a disability (242). Threats from abusers to withdraw assistive devices, such as wheelchairs and respirators, as well as personal assistant services add to the fears of disabled women and further inhibit their disclosure of violent incidents. These threats and fears also serve as disincentives to leave abusive relationships with caregivers and family members and reinforce the cycle of violence. Other experts speculate that a lifetime of negative encounters with law enforcement, judicial and social systems, coupled with a fear of becoming institutionalized or other losses of self-autonomy, may prevent victims with disabilities from disclosing encounters of abuse and violence (243–245).

Past research exploring sexual abuse among women with physical disabilities, compared to women with developmental disabilities, showed that sexual assault among women with physical disabilities is commonly perpetrated by male strangers rather than acquaintances or family members (as is often the case with women with developmental disabilities) (236). However, a recent study of 16,672 women survivors of sexual assault that studied sexual assault patterns among women with and without disabilities, which included a sample of 1,711 women from a range of disability specific groups, including mental health disabilities, physical, sensory, and cognitive disabilities, revealed that the majority of assailants for all groups were known assailants. Other significant findings included that the survivor's home was the most frequently reported setting for assault among all groups and that former and current partners "represented significantly greater proportion of assailants for women with physical disabilities, or hearing impairments, and the least for women with cognitive disabilities." An unexpected finding of the study underscored that the average time from assault to reporting the abuse does not differ significantly between women with and without disabilities or between disability-specific groups. However, the researchers speculate that women with disabilities may be more likely to tolerate more abuse before they seek support (246).

Health care providers are cautioned to discriminate between the signs of sexual abuse and those of disability. Frequently, symptoms of abuse are confused with the sequelae of a woman's disability, or they may be overlooked completely. Common symptoms of sexual abuse include pain, bruises, and bleeding in the genital area, behavioral disturbances, loss of weight, fear of sexual intimacy, and fear of intervention (8). Practitioners are also urged to be mindful in recognizing and treating the symptoms of posttraumatic stress syndrome (PTSD), which can manifest in survivors of violence. When she has had previous brain trauma acquired through violence, the compounded effects may overwhelm the woman and require physicians to invoke the expertise of mental health workers familiar with such cases.

Moreover, physicians must take a supportive and facilitative role in identifying and treating violence and abuse. Many states have mandatory reporting laws that require health professionals to report incidents of abuse detected in their disabled patients or clients. Since the specifics of these laws can vary from one state to another, it is essential that health providers educate themselves

about their responsibilities as mandated reporters. If a provider is mandated to report on abuse of a woman with a disability, without her knowledge, the implications for the woman can be uncertain. Some women may risk institutionalization or the loss of custody of their children if they are not engaged with the provider/reporter in a problem-solving process before the report is made to the authorities. It is therefore important for providers to become familiar with local domestic violence or disability advocates who can help collaborate and advocate with the disabled abuse victim in an empowering fashion that promotes legal compliance, safety, and self-determination. As pioneers of domestic violence advocacy remind us, domestic violence requires practitioners to move beyond the biomedical model and collaborate with advocacy groups committed to ending violence against women. They can assist by working to facilitate access to high-quality personal assistants and to increase living options beyond nursing homes and other institutional facilities. Health care providers can help prevent sexual abuse in women with disabilities by collaborating with other social services to develop comprehensive outreach strategies that are accessible to women with physical, cognitive, sensory, and communication disabilities, including those living in institutions.

Offering high-quality health services to disabled women obliges providers to make their services welcoming, with accessible equipment, signers, and TTYs (teletype writers). It also dictates that they become knowledgeable about local accessible shelters and their policies regarding personal assistants and children. Shelters and support services are accessible only if they can be accessed by a woman at any time regardless of her physical, sensory, or communication disabilities. Physicians should be aware of their role in breaking the cycle of violence and disability. They are encouraged to work with disabled women's centers and social services to prevent isolation to the fullest degree by involving the expertise of disabled women in the design and execution of outreach and safety planning strategies. For example, transportation is a key component in any emergency. It should be factored into all safety plans. For practitioners who are interested in grasping the details of comprehensive safety planning procedures and solutions, a protocol has been developed by The Washington State Coalition Against Domestic Violence for the following disabilities: cognitive, sensory, mental health, mobility disabilities, and hidden disabilities (243). Most important, health providers can assist in breaking the cycle of violence and disability by implementing a system of detection, reporting, and prosecution for cases of assault. Assaults will continue unless practitioners are willing and able to implement a comprehensive protocol (247).

## CONCLUSION

Women with disabilities are finding their voices and making change happen. Empowered by their belief in their intrinsic worth and potential, they are tirelessly pursuing unjust policies, antiquated and ignorant attitudes, and exclusionary systems. It is unconscionable, though, that it is often done, not with

the help of, but often in spite of powerful social institutions such as health care. How is that almost two decades after passage of the ADA, women with disabilities often still feel they do not belong, shuttled between primary care, reproductive health and rehabilitation providers, each feeling ill-prepared to address the woman's health care needs in the context of her disability. The reasons given are many. It may be the inaccessible office, the poorly trained staff, the discomfort with one's lack of knowledge and experience, but the result is the same: exclusion. To address the resultant health care disparities, poor quality care, preventable secondary morbidities, and our systems of care and training programs must change, and HCPs need to lead the charge. Health care institutions and educational programs need to recognize that disability is part of life, must be taught and planned for, and that universal design principles should be the standard. Researchers need to gather information about disability-specific variables when studying general health conditions, in order to further our understanding of common medical conditions in the context of disability. This does not mean that all care providers need to provide care to all. Interdisciplinary and collaborative care in our ever specialized world of medicine is here to stay. But it does mean recognizing that women with disabilities are first and foremost women and need to have their basic health care needs addressed in a competent and inclusive fashion. The narrative of exclusion in the health care setting is a tiresome one; we need a new narrative for the next edition of this textbook, full of creativity, possibilities, and progressive models of care—and each reader of this chapter can help to write it!

## ACKNOWLEDGMENT

The authors would like to acknowledge the following people who were very generous with their time, resources, and expertise in advising on the new edition of this chapter. Specifically, we thank Megan Kirshbaum PhD, Judi Rogers OTR/L, and Christi Tuleja MS, OTR/L from *Through the Looking Glass* for their expertise on parenting and child care for women with disabilities. Rosemary Hughes PhD provided valuable advice on domestic violence and women with disabilities. We would like to thank Chris Wisniewski, MSW, Katrina Bullock and Rebecca Thompson from the RIC Women with Disabilities Center who provided technical assistance. And finally, we would be remiss if did not acknowledge the invaluable contributions of the authors involved in the earlier versions: Carol J Gill PhD, and the late Sandra Welner MD. Their influence, passion, and wisdom are still palpable in this updated chapter.

# Aging and Rehabilitation

Aging, an integral part of living, is typically accompanied by gradual but progressive physiologic changes and an increased prevalence of acute and chronic illnesses. Although neither a disease nor a disability *per se*, aging nonetheless is associated with a higher incidence of physical impairment and functional disability. Many of these functional difficulties occur from the interactions of decreased physiologic reserve with chronic illness. Ongoing research suggests effective interventions to prevent, delay, minimize, or reverse such physiologic declines (1,2). Appropriate roles for geriatric rehabilitation accordingly include not only intervening to reverse disability caused by specific disease or injury (e.g., stroke, hip fracture) but also contributing to preventive gerontology by virtue of promoting structured physical fitness (i.e., wellness) programs and early rehabilitation for common musculoskeletal disorders to avoid progression to disability (1–4).

Significant contributions of rehabilitation to care of older adults include functional assessment (including evaluation of underlying impairments contributing to functional loss and disability) with realistic goal setting, interdisciplinary team care, and efficacious adjustment of therapy interventions (e.g., timing, setting, intensity) to prevent, reverse, or minimize disability (2,5,6). Given the burgeoning number of older persons living longer, Rusk's observation, as modified by Kottke, becomes ever more relevant: "As modern medicine adds years to life, rehabilitation becomes increasingly necessary to add life to these years" (7).

The goals of this chapter are to:

- Discuss relevant aspects of epidemiology and physiology of aging
- Examine the impact of the environment on function in older adults
- Review data on patterns of functional decline in older adults, with particular attention to the effects of hospitalization
- Identify general principles of assessing functional loss as a basis for formulation of rehabilitation plans of care
- Detail appropriate rehabilitation interventions for a number of disabling clinical syndromes and conditions that occur frequently in older adults.

## AGING—EPIDEMIOLOGY AND PHYSIOLOGY

### Demography and Epidemiology of Aging Demographic Imperative

The context for the increasing interest, and concern, about health care needs of older adults is found in demographic projections of an expanding elderly population in the United States

and other developed countries. At the turn of the 20th century, one of every 25 Americans (4%) was 65 years of age or older. By 1994, this population had increased to one of every eight Americans (12.6%), or 33.2 million (8,9). While the elderly population grew 11-fold during this interval, the under-65 population only increased by a factor of three. Current projections indicate that 86.7 million, or one of every five Americans (20.7%), will be 65 years of age or older by the year 2050 (10). By 2029, all "baby boomers" (Americans born post-WW II, between 1946 and 1964) will be 65 years or over (10). Between now and 2030, the fastest growing segment of the population will be the 65 to 74 year olds, increasing from the current 6.3% to 10.4%. Between 2030 and 2050, however, the 75+ population will outpace the 65 to 74 cohort, reaching 11.6% of the population (every ninth American), while the 65 to 74 year olds will account for 9.0% (10).

Distribution of the elderly is uneven across the United States, with 50% living in just nine states. While California has the greatest number of citizens over the age of 65, Florida has the highest proportion of elderly (18.6%) (8). There are also ethnic aging trends, with projections that by 2050 the proportion of older white individuals will have decreased to 67% (from 87% in 1990), with corresponding increases of older Hispanic and black American citizens of 16% and 10%, respectively.

This demographic phenomenon is not limited to the United States, as a number of developed countries (including Italy, Japan, Germany, Sweden, and Great Britain) show 20% or more of their populations over age 65 (8). As of 1994, there were 357 million older people worldwide, representing 6% of the total population.

There is increasing recognition of differences in health care needs and issues among subgroups of older people. Of particular significance from a health care standpoint is the rapidly expanding relative proportions of the population age 65 years and older who are 75 to 85 years of age (old old) and 85 years of age or older (oldest old). These groups include many of the so-called "frail elderly," with a disproportionately high prevalence of disabilities and consumption of health services (11). Another related dynamic is recognition of increasing racial and ethnic health disparities among older Americans, as the relative proportions of racial and ethnic minorities increase: from 2003 to 2050 the proportion of Non-Hispanic whites will decrease from 83% to 61%, while Hispanics will increase from 6% to 18%, blacks from 8% to 12%, and Asians from 3% to 8% (12).

### Compression of Morbidity

Older people also are living longer: 1990 statistics estimated a longevity at 65 years of age of 15.0 years for men and 19.5 years for women; this is projected to increase further to 17.1 and 22.6 years, respectively, by the year 2040 (13). Contributing factors to these increases in longevity include improved access to health care, advances in medical care, overall healthier lifestyles, as well as better health prior to age 65 (14). The increasingly delayed occurrence of death at all ages appears in part to be due to reduced lethality of such diseases as stroke, cancer, and myocardial infarction, resulting from risk factor reduction as well as improved health care interventions (9). Increasingly, people are surviving their initial encounter with these previously fatal diseases, resulting instead in chronic illness. This trend has been termed the fourth stage of epidemiologic transition (i.e., the postponement of death from degenerative diseases) (15). These significant reductions in mortality are associated with an increasing risk for development of various chronic diseases. Certainly, the incidence and prevalence of many potentially disabling chronic illnesses increase substantially among older adults, including arthritis, osteoporosis with associated fractures, stroke, amputation, and various neurodegenerative disorders (e.g., Alzheimer's disease, Parkinson's disease) (2,10,11,13).

This demographic imperative has far-reaching implications for increasingly limited U.S. health care resources and dollars: current national direct cost of medical services for older individuals with chronic conditions is in excess of \$470 billion (in 1990 dollars), with a projected near doubling by the year 2050 (13). In 2004, the average annual health care expenses were \$8,900 for the 65+ population, compared to \$3,028 for the under 65 population (10). The old-old and oldest-old groups consume the greatest proportion of resources, and a disproportionate amount of these health care costs represent nursing home and other institutional care (11). While the overall proportion of elderly individuals residing in nursing homes decreased from 6.8% in 1982 to 4.2% in 1999, these rates vary dramatically by age (16). Only 1% of young old (65 to 74 year olds) reside in nursing homes, contrasted with 20% of the oldest old (85 years of age or older) (9). In fact, the latter group comprises 45% of all elderly nursing home residents.

From another perspective, however, the vast majority of the 85-or-older population is not in nursing homes, and half of those in nursing homes do not necessarily need to be there because they have potentially preventable (or reversible) disabilities related to their chronic disorders (17). In fact, it appears that much of the increased health care cost associated with aging (across all health care settings) is significantly related to activity limitation, rather than chronic disease (18). Fortunately, there is increasing evidence that disability among older individuals may be decreasing (16,19). Reports of limitation of activity due to a chronic condition in the 65+ population have continued to decrease, from 38.7% in 1997 to 32.6% in 2006 (12).

These findings continue to lend credence to the concept advanced by Fries in 1980 of "compression of morbidity," in which he predicted that if the age of onset of disability could be significantly delayed (e.g., with regular exercise, healthier diets,

elimination of smoking, improved health care interventions) in the context of a relatively "fixed" life span, then terminal predeath disability could be compressed into a shorter interval (20). He postulated that health care needs for older people would decrease because they would be relatively healthy and functional until shortly before their death. A related prediction was that this anticipated short duration of predeath morbidity, and accompanying disability, would be expected and accepted with acknowledged futility of medical intervention. There is consistent evidence of increased health care costs associated with aging, with one study documenting nearly one half of lifetime health care costs occurring after age 65 (21). Interestingly, although a number of reports have documented dramatically increasing health care costs near the end of life, it should be noted that these are costs of dying, not of aging *per se* (22). Further, there is evidence suggesting that the incremental costs associated with extending life may actually plateau or even decrease (23–25). These findings are of critical significance in the context of increasing focus on cost containment and debate over the feasibility and appropriateness of rationing of health care (26). Twenty years after his initial predictions, Fries (and others) cites increasing evidence in support of the trend of compression of morbidity, even though the mechanisms are not clear (27,28). He reiterates the importance of a research agenda focused on delineation of the epidemiology of disability, determination of the fundamental basis of age-associated chronic conditions, and identification of effective interventions for preventing or delaying resulting disability (27). This call to action has been echoed by others as well (1,2,21). On the other hand, Kane raises disturbing questions regarding potentially adverse economic, cultural, and individual consequences of successfully overcoming the aging (and dying) process and urges ongoing dialogue to further explore these ethical questions (29).

### Active Life Expectancy

A derivative of research into longevity and epidemiology of aging relates to issues of quality of life, given the increased incidence of frequently disabling chronic disorders such as degenerative neurologic diseases (e.g., Alzheimer's disease, Parkinson's disease), degenerative musculoskeletal conditions (e.g., osteoporosis, osteoarthritis), and multisensory losses (e.g., cataracts, presbycusis). One concept that attempts to delineate quality of life for older individuals has been termed "active life expectancy," referring to the proportion of remaining life span characterized by functional independence (30). This concept, also referred to as "disability-free life expectancy," has been expanded to consider both physical and cognitive impairments, as well as their interrelationships (28,31). A significant gender difference in active life expectancy with aging has been identified. As can be seen in Table 59–1, older men have a greater proportionate active life expectancy at all ages. However, due to greater longevity, older women enjoy longer actual durations of active life expectancy than older men, until age 85 (31,32). A recent longitudinal British study confirmed a gender difference, with men aged 65 showing 79% active life expectancy (12.1 of 15.3 years) and women aged 65 showing 57% active life expectancy (11.0 of 19.4 years) (28). Further investigation into

**TABLE 59.1** Active Life Expectancy (Remaining Years of Functional Independence, Compared to Projected Longevity) by Gender and Age Cohort

Age	Males	Females
65	82% (11.9 of 14.4 y)	73% (13.6 of 18.6 y)
85	50% (2.6 of 5.2 y)	35% (2.3 of 6.4 y)
95	20% (0.6 of 3.2 y)	10% (0.4 of 3.7 y)

Adapted from Manton KG, Stallard E. Cross-sectional estimates of active life expectancy for the U.S. elderly and oldest-old populations. *J Gerontol*. 1991; 46(suppl):170–182.

dynamics impacting active life expectancy reveals the deleterious effects of diabetes (decreased total life expectancy and active life expectancy at all ages, with a 25% reduction in active life expectancy in 85 year olds) and depression (reduction of active life expectancy by 6.5 years in 70-year-old males and by 4.2 years in 70-year-old women) (33,34).

### Comorbidity, Frailty, and Disability

Although the increasing incidence and prevalence of (often multiple) chronic diseases with aging is well documented, there is no one-to-one correlation between either disease and illness (35) or disease and disability (19). A significant proportion of older people are limited in the amount or kind of their usual activity or mobility secondary to chronic impairments: over 60% of adults with functional impairments due to chronic health problems are 65 years of age or older (13). However, disability in this older population can also be very dynamic, with frequent

transitions between periods of independence and disability and levels of disability (36,37). Also, the overall health of progressive cohorts of older persons has been changing. Although there have been predictions that future generations may well be healthier than current generations, due in part to higher levels of education and health awareness (36), there are disturbing trends of increasing obesity and diabetes in older adults, with significant associated morbidity and mortality (10).

Fried et al. have helped to clarify the dynamics of interrelationships among comorbidity, frailty, and disability—terms frequently used interchangeably—by providing discrete definitions of each entity and describing the synergistic impact of each on the other(s) (38). As seen in Figure 59–1, *Disability* accordingly is defined as “difficulty or dependency in carrying out activities essential to independent living” (such as activities of daily living [ADLs], mobility, instrumental activities of daily living [IADLs]), while *Frailty* is “a physiologic state of increased vulnerability to stressors that results from decreased physiologic reserves, and even dysregulation, of multiple physiologic systems.” Frailty appears to represent an aggregate expression of risk resulting from age- or disease-associated physiologic accumulation of subthreshold decrements affecting multiple physiologic systems (38). Fried cites evidence in support of a phenotype of the clinically frail older adult, characterized by the presence of a critical mass of three or more “core elements” of frailty (weakness, poor endurance, weight loss, low physical activity, and slow gait speed) (39). *Comorbidity* is commonly defined as the concurrent presence of two or more disease processes in the same individual. Fried suggests that comorbidity is the aggregation of clinically manifested diseases present in an individual, while frailty is the aggregate of subclinical losses of reserve across multiple physiologic systems (38).

**FIGURE 59-1.** Definitions of frailty, comorbidity, disability. (From Fried LP, Ferrucci L, Darer J, et al. Untangling the concepts of disability, frailty, and comorbidity: implications for improved targeting and care. *J Gerontol Med Sci*. 2004;59(3):255–263.)

Prevalences—and overlaps—of comorbidity, disability, and frailty among community-dwelling men and women 65 years and older participating in the Cardiovascular Health Study. Percents listed indicate the proportion among those who were frail ( $n = 368$ ), who had comorbidity and/or disability, or neither. Total represented: 2762 participants who had comorbidity and/or disability and/or frailty. \* $n = 368$  frail participants overall. \* $n = 2576$  overall with 2 or more of the following 9 diseases: myocardial infarction, angina, congestive heart failure, claudication, arthritis, cancer, diabetes, hypertension, chronic obstructive pulmonary disease. Of these, 249, total were frail. \*\* $n = 363$  overall with an activity of daily living disability; of these, 100 (total) were also frail.

**FIGURE 59-2.** Overlap of frailty, comorbidity, disability. (From Fried LP, Ferrucci L, Darer J, et al. Untangling the concepts of disability, frailty, and comorbidity: implications for improved targeting and care. *J Gerontol Med Sci.* 2004;59(3):255–263.)

Fried further documents the interrelationships between frailty, comorbidity, and disability (Fig. 59–2), noting that frailty and comorbidity each predict disability, while disability appears to exacerbate frailty and comorbidity (38). While medical care for each of these entities is typically complex, particularly when they coexist, Fried specifically notes that rehabilitation interventions for disabled older adults to regain function and/or prevent further functional decline need to factor in recognition and treatment of frailty and comorbidity to maximize likelihood of success. She cites growing evidence to suggest that frailty, comorbidity, and disability may be preventable, but with different intervention strategies (38). The importance of prevention is reinforced by the clear association of each entity, especially when concurrent, with higher health care costs and poorer survival (38,40). Recent research is further differentiating between various subtypes of disability in older individuals (transient, short-term, long-term, recurrent, and unstable) and their relative clinical significance (41).

In summary, an increasing proportion of older people are living longer and are at increased risk of developing varying (and changing) degrees of comorbidity, frailty, and functional losses with disability. The challenge for health care providers, accordingly, is to try to prevent the onset/progression of these entities with early and effective medical and rehabilitation

interventions, to reverse or at least minimize their deleterious effects on health and function.

### Successful Aging

Distinctions have been made between aging processes representing “primary aging” (i.e., apparently universal changes that occur with aging, independent of disease and environmental effects) and “secondary aging,” which includes lifestyle and environmental consequences and disease associated with the aging (42,43). A number of tenets associated with aging research are being reexamined, particularly with the observation that a pathologic process may exaggerate an aging process believed to be normal, even before the disease is detected clinically (42). There is increasing evidence that the nonpathologic processes of aging are distinct from, but not necessarily independent of, the pathologic processes of disease (38,44).

Most studies of normal aging have focused on the physiological and biochemical changes occurring with aging, with explicit exclusion of disease. However, it is increasingly apparent that such factors as personal habits (e.g., diet, exercise, nutrition), environmental exposures, and body composition may have significant impact on observed aging changes (43). Rowe has proposed a conceptual distinction between “successful aging” and “usual aging” (45). He suggests that “successful aging” could be characterized by minimal or no physiologic losses in a particular organ system and would comprise a relatively small subset of the total “normal” (i.e., nonpathologic) aging population. The remaining majority of “normal” older adults demonstrate “usual aging,” with gradually progressive but significant declines in various physiologic functions.

The significance of this concept lies in the implications for modifiability of usual aging by virtue of addressing such variables as level of physical activity, diet and nutrition, and environmental exposures (27,43,44). This principle is demonstrated in studies documenting the effects of exercise, diet, and drugs on the usual aging observations of carbohydrate intolerance. Rowe proposes that geriatric research into health promotion initiatives concentrates on increasing the proportion of older adults who “successfully age” by identifying and modifying extrinsic risk factors contributing to “usual aging” and decreasing the manifestations of “pathologic aging” by preventing or minimizing adverse effects of acquired disease processes (45). This would reinforce the previously described concept of compression of morbidity, with greater active life expectancy. Indeed, studies are helping to determine which factors distinguish high-functioning older adults from other populations of older adults (28,33,43,46).

### Theories of Aging

With continuing research, it appears likely that there is no single cause of aging (44,47). The current concepts of aging characterize the process as extremely complex and multifactorial and suggest that various theories of aging should be viewed not as mutually exclusive, but rather complementary (47). From this perspective, hypotheses based on passive (i.e., random) and/or active processes of genetic programming could be considered in conjunction with superimposed nongenetic

mechanisms (e.g., environment, lifestyle), producing varying individual vulnerability (42,44,45,48). Certainly this would help explain the well-documented phenomenon of differential aging, whereby individuals of the same species appear to age at different rates (44,46). Multiple levels of research suggest that rates of aging are affected to varying extents by heredity, lifestyle, environment, occurrence of disease, and psychological coping abilities (17,32,42,46).

Active investigation continues in the areas of neuroendocrine pacemakers, telomere shortening, and attenuation of inducible stress responses (48–51). A number of studies have also focused on the phenomena of apoptosis and autophagy, related to cell death of proliferating and postmitotic cells respectively, as well as mitochondrial degradation in long-living cells (52,53). There is some evidence suggesting that pathologic stimulation of apoptosis may result in a number of degenerative disorders commonly associated with aging, whereas inhibition appears to be associated with a variety of forms of cancer (52).

### Physiology of Normal Aging

The normal aging process involves gradual decreases in organ system capabilities and homeostatic controls that are relatively benign (i.e., asymptomatic or subclinical) in the absence of disease or stress (35). Although the older person progressively adapts to these changes without need (or desire) for outside intervention, the steady decreases of physiologic reserves make older adults potentially vulnerable to functional decline as a result of acute and/or chronic illnesses (42,54).

Characteristics of aging include:

- Decreased reserve capacity of organ systems, which is typically apparent only during periods of exertion or stress
- Decreased internal homeostatic control (e.g., blunting of the thermoregulatory system, decline in baroreceptor sensitivity)
- Decreased ability to adapt in response to different environments (e.g., vulnerability to hypothermia and hyperthermia with changing temperatures, orthostatic hypotension with change in position)
- Decreased capacity to respond to stress (e.g., exertion, fever, anemia) (35)
- The end result of these age-related declines is an increased vulnerability to disease and injury, or *frailty* (38).

### Problems in Study Design

Inherent with studying physiologic changes in aging adults are several potentially confounding variables, which are unique to this population. Awareness of these dynamics will facilitate more accurate interpretations of clinical studies of older adults, with particular reference to generalizability.

### Definition of Normal

A significant concern, in view of the heterogeneity of the aging population, is what is truly normal. As noted, there is great variability in rates of aging among healthy elderly and wide variations in individual performance. Further complicating any

analysis is a superimposed dispersion of skills due to frequency of significantly impaired function from disease, environment, and lifestyle (32,35). More than 80% of the population over 65 years has at least one chronic disease and 50% two or more disorders (31). Of concern is whether the relative minority of older people who have escaped serious illness should be considered “normal” for the purpose of studies of aging and whether the results of such studies can be generalized to the rest (majority) of the older population.

On the other hand, it is important clinically to be able to differentiate the physiologic consequences of aging (i.e., normal aging) from those of accompanying disease (i.e., pathologic aging) (3). Because detection of disease depends on determination that a patient is other than normal, it is critical to define appropriate age-adjusted criteria for clinically relevant variables in the elderly (55). Although many laboratory values do change gradually with aging, abnormalities should not be *a priori* attributed to old age. In fact, a number of age-related changes may resemble the changes associated with a specific disease (44). For example, an age-related decline in glucose tolerance is well documented. So dramatic is this change that most people over 60 years of age would be diagnosed as diabetic if traditional criteria, based on studies of primarily younger patients, were applied (56).

### Methodology Limitations

A number of methodological problems are associated with the study of aging. Well recognized are frequent discrepancies in age reporting, with a tendency to distort upwardly (57). This is coupled with difficulties in verifying reported ages, due in part to lost or nonexistent birth records.

Another major problem in the design and evaluation of aging studies is the relative validity of both cross-sectional and longitudinal studies. Cross-sectional studies, although easier and less costly (in time and money) to perform, often overemphasize (but may also underestimate) age-related changes (58,59). This can result from a cohort bias, due to significant differences in educational, nutritional, health, and social experiences of people born in different decades. Contributing further to this distortion is the high proportion of elderly in the United States who were foreign born, with relatively less schooling. This has implications in particular for studies of psychological and cognitive changes with aging (19).

On the other hand, longitudinal studies tend to underestimate changes due to aging, primarily as a result of withdrawal and survivor biases with high drop-out rates (46,54,58). Some studies have experienced as much as a 50% drop-out rate over just a 10-year period, leading to questions of self-selection for relative preservation of function (and again, the issue of “super-normals”). Subtle changes in methodology over time may introduce laboratory drifts that are difficult to differentiate from true age-related changes (8). A further concern with serial measurements is the potential for distortion due to learning effects.

### Mean Versus Maximal Performance

Another issue in the characterization of aging is that a focus on “average” or “mean” changes in various parameters can

hide remarkable individual variation, particularly regarding peak performance (20). Consider marathon running, which tends to attract a very select (“supernormal”) population, and, thus, individuals with a higher maximal aerobic capacity. For example, a 50-year-old male with a marathon time of 3.5 hours is in the 99th percentile for his age group, yet this same time would not be an age group record until over 80 years of age. Although there also is a slow linear decline in maximal aerobic performance with aging based on world age-group records, this is only on the order of about 1% per year between the ages of 30 and 70 years (20).

### Effects of Age on Organ System Performance

There are several general principles regarding aging effects on the performance of various organ systems (60).

#### *Wide Individual Differences in Rate of Aging*

Variation between healthy people of the same age is far greater than the variation due to aging alone, and the range of variability increases with aging (20). Linear regressions show average changes with aging, but variation between subjects is so great that it is not always possible to determine accurately if age decrements are linear over the entire age span or whether the rate of decline accelerates in later years (61). However, Fleg et al. recently reported that  $\text{VO}_{2\text{max}}$  declines more precipitously after the age of 70, especially in men, irrespective of habitual physical activity (62).

#### *Different Organ Systems Age at Different Rates*

There is great individual variation in the rate of decline for various organ system functions (35). For instance, there is up to a 60% decline in maximal breathing capacity with aging but only a 15% decline in nerve conduction velocity and basal metabolic rate during the same time interval. Another demonstration of this principle is the localized cellular growth, aging, and death that occur continuously in some tissues and organs (e.g., hematopoietic system, skin, mucosa). Furthermore, a significant decline in function of one organ system (e.g., kidney) does not necessarily entail a similar decline in other organ systems (60).

#### *Age Changes with Complex Performances*

Complex performances (e.g., running) will show greater changes with aging because of the need to coordinate and integrate multiple organ system functions (e.g., rate, degree and sequence of muscle contraction, balance, proprioception, vision, cardiovascular response), as opposed to simple performances involving a single system (e.g., renal glomerular filtration) (60).

#### *Age Changes in Adaptive Responses*

Adaptive responses (e.g., to temperature change or change in position) are most affected by aging due to a decline in the effectiveness of physiologic control mechanisms (e.g., sensory feedback), which is magnified during stressful situations (e.g., disease, sudden changes in environment) (35,60).

### Prevention and Reversibility of Physiologic Decline

There is little question that biologic systems, regardless of the direct effects of aging, can be profoundly influenced by environment and lifestyle (32,35,43). Obvious examples include the deleterious effects of smoking and a sedentary versus active lifestyle (63,64).

The modifiability or plasticity of aging is demonstrated by studies in which performance can be improved despite age, within relatively broad ranges (20,65). Physical training can improve or even reverse age-related declines in aerobic power and muscle strength (66–68). These gains have been demonstrated to translate to improvements in functional skills (69,70).

### Functional Implications of Organ System Aging

The clinician must be aware of specific age-related physiologic changes to properly understand disease in the elderly because these changes significantly influence not only the presentation of disease but also the response to treatment and potential complications that may ensue. Similarly, such knowledge is essential to understand the underlying mechanisms of functional deterioration secondary to disease and to formulate effective rehabilitation approaches (3). The following is a summary of clinically significant physiologic changes that occur with aging.

#### *Hematologic System*

Although anemia (i.e., hemoglobin <13 g/dL in men and <12 g/dL in women) (71) occurs with increasing prevalence with aging, there is convincing evidence that it is not a normal consequence of aging and should be investigated, especially if hemoglobin is less than 10.5 g/dL (72–74). Anemia in older people appears to be due most commonly to iron deficiency (typically from GI blood loss) or chronic disease (such as infection, polymyalgia rheumatica, or cancer) (73). Other potential causes include hemolysis (e.g., secondary to lymphoma, leukemia, or medication effect),  $\text{B}_{12}$  deficiency (pernicious anemia, diet), or folate deficiency (diet). Of note, D-dimer levels have been shown to double with aging, with even more dramatic increases among blacks and functionally impaired older individuals (75). Increases in the erythrocyte sedimentation rate and C-reactive protein levels also have been noted with aging (76,77).

The functional consequences of anemia can be significant because of further reduction of reserve capacity, such that previously subclinical disease states may become symptomatic (e.g., orthostatic blood pressure changes, change in anginal pattern with lower exercise tolerance) (74,78). This has obvious implications with regard to tolerance of relatively intensive and sustained rehabilitation exercise programs. There is also evidence of correlation of even relatively mild anemia with impaired mobility (79,80). A very anemic older patient may present with nonspecific fatigue and confusion, with the potential for misdiagnosis and mistreatment (72).

There are several related hematologic changes with aging that can affect pharmacokinetics, particularly drug distribution. Decreased drug binding for highly protein-bound drugs (e.g., warfarin, meperidine, tolbutamide) may result in a higher

unbound, or free, drug concentration with correspondingly magnified actions (81). This effect is even more significant for patients taking multiple drugs because of competition for fewer binding sites.

The volume of distribution is also altered in older adults due to a reduction in total body water and lean body mass, with a relative increase in body fat (82). As a result, water-soluble drugs (e.g., digoxin, cimetidine) tend to have a smaller volume of distribution, with higher plasma concentrations and greater pharmacological effect (83). Conversely, fat-soluble drugs (e.g., diazepam, phenobarbital) usually have a larger volume of distribution because of relatively greater storage in fatty tissue. This may result in delayed therapeutic effects, with the potential for unexpected late toxicity. By the same token, prolonged drug effects are seen after dosage change or discontinuation because of the amount of drug stored in adipose tissue (81).

### ***Gastrointestinal System***

The term “presbyesophagus” has been used to describe multiple changes in the esophageal function commonly observed with aging, such as delayed esophageal emptying, incomplete sphincter relaxation, and decreased amplitude of peristaltic contractions. Only the latter appears to be a direct result of aging, but it is not clinically significant; the other changes are related to associated disease processes and may have significant clinical ramifications (84). Most importantly, there is an increased risk of aspiration with aging due to less coordinated swallowing.

Age-related changes occur throughout the gastrointestinal (GI) system although the more distal portion is most affected (85). Alterations in colon function include slightly decreased force and coordination of smooth muscle contraction resulting in slower transit time, as well as impaired rectal perception of feces (86). The high incidence of constipation in older people accordingly is thought to be related to multiple additional factors, such as low dietary fiber and fluid intake, sedentary habits, and various associated diseases interfering with intrinsic bowel function (e.g., parkinsonism, stroke) (87). A variety of medications are potentially constipating as well, including minerals (e.g., aluminum antacids, iron, calcium), opiates, nonsteroidal anti-inflammatory drugs (NSAIDs), antihypertensives (e.g., calcium channel blockers, clonidine), anticholinergics (e.g., tricyclic antidepressants, neuroleptics, antispasmodics), and sympathomimetics (e.g., pseudoephedrine, isoproterenol, terbutaline) (88). Prolonged use of stimulant laxatives or enemas can also impair bowel contractility and result in constipation or obstipation (87). Older adults often report straining and hard bowel movements along with their constipation (89). Straining may indicate rectal dyschezia (i.e., impaired rectal sensation and contractility).

Fecal incontinence in older people is due most commonly to overflow incontinence secondary to fecal impaction but can also occur as a result of decreased sphincter tone, cognitive impairment (e.g., from drugs, dementia), diarrhea, or dyschezia (87,89). Diarrhea among elderly patients is most frequently caused by fecal impaction, intestinal infection, or drugs (e.g., broad-spectrum antibiotics, digoxin toxicity) but also can

be due to chronic laxative abuse (90). More appropriate interventions for bowel regulation include increasing diet fiber, using bulk agents or stool softeners, and avoiding frequent use of enemas or laxatives.

Despite these physiologic changes with aging, little effect is seen on absorption of most orally administered drugs (83). Drug absorption in general is more significantly affected by concomitant administration of multiple drugs; in particular, antacids and laxatives bind to or reduce dissolution of other medications (81).

### ***Hepatic System***

The primary changes in the hepatic system with aging involve a gradual progressive decline in liver size (5% to 15%) and hepatic blood flow, as well as slowing of hepatic biotransformation, specifically and most consistently microsomal oxidation and hydrolysis (83,86). This can have major implications on the circulating concentration of certain drugs and their metabolites, depending on the mode of metabolism and clearance. Drugs with high first-pass clearance (e.g., propranolol, propoxyphene, major tranquilizers, tricyclic antidepressants, antiarrhythmic drugs) are cleared less effectively owing to reduced hepatic blood flow, resulting in greater bioavailability (81). Comorbid processes such as congestive heart failure can exacerbate these effects.

Drugs metabolized by means of phase I biotransformation (i.e., oxidation, reduction, hydrolysis) tend to have prolonged elimination in older people (e.g., diazepam, chlordiazepoxide, prazepam), whereas those undergoing phase II metabolism (i.e., glucuronidation, acetylation, sulfation) generally are not affected by aging changes (e.g., oxazepam, lorazepam, triazolam) (81,88).

It is important to note that studies of drug elimination with aging demonstrate significant interindividual variability that is likely due to genetic variation as well as the effects of such factors as smoking, alcohol, caffeine intake, diet, and concurrent use of other medications (83). As a result, caution should be exercised when using age-based guidelines for dosage determination (61).

### ***Renal System***

There are a number of age-related anatomic and physiologic changes in the kidney, including decreases in renal mass, number and functioning of glomeruli and tubules, renal blood flow, and glomerular filtration rate (91–93). These reductions in renal function have major implications for drug excretion, with prolonged half-lives for those drugs cleared primarily by glomerular filtration (e.g., cimetidine, aminoglycosides, digoxin, lithium, procainamide, penicillin, chlorpropamide) (81).

Studies show a mean age-related decrease in renal function of about 1% per year, with a decrease in creatinine clearance of 7.5 to 10 mL per decade; however, there is wide variability, with up to a third of older individuals showing no significant decline (92). Because of a corresponding decline in daily urinary creatinine excretion (reflecting decreases in muscle mass), there is no significant change in serum creatinine level with

aging. As a result, neither serum blood urea nitrogen (BUN) (which is dependent on dietary intake and metabolic function) nor creatinine is valid for accurately gauging renal function in older people (81).

Other common physiologic changes with aging include impaired ability to concentrate and dilute urine, impaired sodium conservation, reduction of urine acidification, and decreased ability to excrete an acid load (91). This erosion of reserve capacity allows maintenance of fluid and electrolyte homeostasis under normal conditions, but not with sudden changes in volume, acid load, or electrolyte balance. As a result, older people are more vulnerable to hyponatremia, hyperkalemia, dehydration, and perhaps most seriously, water intoxication (56,94).

Because of difficulty in concentrating urine in conjunction with a blunted thirst mechanism, a hypernatremic state with attendant mental confusion can result if an elderly person is stressed by higher than usual insensible losses (e.g., high or prolonged fever, heat exposure, exercise) with poor fluid intake (94). This is pertinent in a rehabilitation setting because patients are often engaged in vigorous activities and may become dehydrated relatively easily.

Just as older patients are prone to volume depletion when deprived of salt, acute volume expansion from an elevated sodium load caused by inappropriate intravenous fluids, dietary indiscretion, or intravenous radiographic contrast dye can result in congestive heart failure, even in elderly patients without preexisting myocardial disease (81,95). A further potential complication of the use of radiocontrast materials in the elderly is the risk of acute renal failure, which is exacerbated by the presence of preprocedure dehydration (91). Because renin and aldosterone plasma concentrations are decreased by 30% to 50% in the elderly, with increased susceptibility to hyperkalemia, potassium-sparing diuretics (e.g., spironolactone, triamterene) should be used with great caution (88).

Hyponatremia due to water intoxication may be the most serious electrolyte disorder of older adults (56,94). Most frequently complicating an acute illness, the clinical picture includes nonspecific signs of depression, confusion, lethargy, anorexia, and weakness. Serum sodium concentrations below 110 mEq/L may result in seizures and stupor. The syndrome of inappropriate antidiuretic hormone secretion (SIADH), with water retention and hyponatremia, can occur with infections (e.g., pneumonia, meningitis), strokes, various drugs (e.g., diuretics), or the stress of anesthesia and surgery (92).

### **Pulmonary System**

Although progressive declines in pulmonary function are observed with aging, in the absence of significant pulmonary, cardiovascular, or neuromuscular disease, these declines are reflected primarily as a loss of reserve capacity without major functional limitations at rest (96). However, impaired pulmonary function on spirometric testing does indicate increased risk for subsequent disability and several common causes of death in older people, including cardiovascular disease and chronic obstructive pulmonary disease (COPD) (97,98).

Changes in pulmonary function observed with aging reflect effects of aging *per se* (in the pulmonary as well as cardiovascular and neuromuscular systems) together with the cumulative effects of inhaled noxious agents (especially cigarette smoke and air pollutants) and infectious processes (96). The latter typically have a far greater impact on pulmonary function.

Progressive decline in a number of pulmonary function tests has been documented with aging, including vital capacity, maximum voluntary ventilation, expiratory flow rate, and forced expiratory ventilation (96). These declines reflect aging changes in the pulmonary system combined with those in related organ systems, which are collectively stressed by the maximum volitional inspiration and expiration required to complete the tests. Examples include stiffening of the rib cage from degenerative calcification of costochondral cartilage (i.e., decreased compliance), weakening of intercostal and abdominal muscles, and increased airflow resistance from small airway narrowing due to decreased elasticity (97). Residual volume and functional residual capacity increase, related to the loss of elastic recoil (increased compliance), although total lung capacity remains unchanged.

Normal gas exchange requires both uniform ventilation of alveoli and adequate blood flow through the pulmonary capillary bed. With increasing age, there is a progressive ventilation-perfusion imbalance due to collapse of small peripheral airways with decreased ventilation of alveoli, resulting in a linear decline in  $pO_2$  with aging ( $pO_2 = 110 - [0.4 \times \text{age}]$ ) (96). Due to altered thoracic mechanics,  $pO_2$  in older individuals is lower in the supine position than with sitting or standing. No changes occur in  $pCO_2$  or pH, and oxygen saturation is typically normal or only slightly reduced.

This reduction in arterial oxygen tension is clinically relevant because it represents an additional loss of reserve. Elderly patients are more vulnerable to significant hypoxia from a relatively minor insult (e.g., anemia, congestive heart failure, respiratory infection) or the stress of physical inactivity because they are closer to the steep slope of the oxygen-hemoglobin dissociation curve (96). Blunting of central and peripheral chemoreceptor responsiveness exacerbates this vulnerability further: both hypercapnic and hypoxic ventilatory responses markedly diminish with aging, independent of lung mechanics. There is a significant increase in sleep-related breathing disorders with aging, and this appears to be related to this phenomenon (56).

Maximal oxygen consumption ( $VO_{2\max}$ ), an overall measure of exercise capacity and cardiopulmonary fitness, depends on pulmonary ventilation, cardiac output, peripheral circulatory control (i.e., ability to shunt blood to exercising muscles), and muscle oxidative capacity (i.e., oxygen extraction from the blood). Although a progressive decline in  $VO_{2\max}$  is observed with aging, this does not appear to be on a pulmonary basis (97,99). In fact, it appears that decreases in  $VO_{2\max}$  in older adults with mild to moderate COPD are due primarily to cardiac and peripheral muscle deconditioning resulting from limited activity levels (97). Regular exercise to maintain or improve fitness is critical with aging because it is possible to

improve fitness with training at any age, and this is associated with a reduced vulnerability to stress or disease (and thereby increased active life expectancy) (65,69,100–102). The tendency of physicians and society to tolerate (or even encourage) decreased activity among older people, in conjunction with trends toward obesity and increased recumbency, probably contributes more to poor pulmonary function than aging alone (97,103).

Although most attention regarding the high incidence of pneumonia in the elderly is focused on immunologic declines, there appear to be contributing factors, direct or indirect, relating to the pulmonary system itself. Because many pneumonias result from aspiration of the infecting organism, impaired mucociliary function and decreased chest wall compliance with weaker cough (resulting in impaired ability to clear aspirated material or secretions) likely play a role (96,97). Other nonimmunologic contributing factors may include dysphagia, disruption of lower esophageal sphincter integrity, various esophageal disorders, and reduced levels of consciousness.

### Cardiovascular System

A number of established tenets about the aging cardiovascular system have been revised, based on continuing research using more rigorous methodologies to exclude occult disease and controlling for degree of habitual physical activity. As a result, it now appears that cardiac output at rest and during graded exercise is relatively unaffected by age directly (56,99,104). Although resting heart rate does not change with aging, maximal heart rate with exercise does decrease progressively, related to decreased chronotropic responsiveness to adrenergic stimuli. The clinical formula reflecting this decline in maximal heart rate involves subtracting the age from 220 for men and  $(0.8 \times \text{age})$  from 190 for women (100,104). Decreased inotropic

responsiveness to adrenergic stimulus results in decreased myocardial contractility, with decreased ejection fraction and increased risk of congestive heart failure (105). Maintenance of cardiac output at rest and with modest exercise is accomplished by early involvement of the Frank-Starling mechanism, with increased stroke volume via higher left ventricular end-diastolic volumes (56,104).

Another age-associated change is a decrease in the rate of early diastolic filling, with a much greater dependency on late filling through atrial contraction (104). As a result, older people are more vulnerable to deleterious effects of atrial tachycardia or fibrillation, including congestive heart failure (99,105).

Both cross-sectional and longitudinal studies demonstrate decreases in maximal oxygen consumption with aging, regardless of habitual activity levels (63,99,106). However, physically active people retain significantly greater maximal aerobic capacity with aging compared to their sedentary counterparts (65). In fact, trained elderly subjects may have greater maximal oxygen consumption than sedentary subjects who are much younger (66). Furthermore, endurance training, even when begun in old age, can significantly improve exercise capacity (65,100). Of clinical relevance is that the energy of walking represents an increasing percentage of the total aerobic capacity with advancing age, such that walking becomes a very effective physical conditioning activity (107).

A final age-related physiologic change in the cardiovascular system with important clinical applications is decreased baroreceptor sensitivity (107,108). This results in a diminished reflex tachycardia on rising from a recumbent position and accounts in part (possibly along with blunted plasma renin activity and reduced angiotensin II and vasopressin levels) for the increased incidence of symptomatic orthostatic hypotension in the elderly (Table 59–2), as well as cough and micturition syncope syndromes (104,109).

**TABLE 59.2 Office Management of Orthostatic Hypotension**

- Orthostatic hypotension is defined as a reduction in systolic blood pressure of at least 20 mm Hg or diastolic blood pressure of at least 10 mm Hg within 3 minutes of assuming an erect posture. However, the significance of any decrease in blood pressure upon standing should be evaluated in context with associated symptoms.
- Regardless of whether orthostatic hypotension is symptomatic or asymptomatic, the elderly patient remains at significant risk for future falls, fractures, transient ischemic attacks, and myocardial infarction.
- Orthostatic hypotension can be acute or chronic. Acute causes include hypotensive medications, dehydration, and adrenal insufficiency. Chronic causes can be further sub-divided into those related to aging or age-related blood pressure elevation (physiologic causes) and those due to central or peripheral autonomic nervous system diseases (pathologic causes).
- The diagnostic evaluation of orthostatic hypotension should include a comprehensive history and physical examination, careful blood pressure measurements, and laboratory studies.
- Goals of treatment in the elderly patient include ameliorating symptoms, correcting any underlying cause, improving the patient's functional status, and reducing the risk of complications, rather than trying to attain an arbitrary blood pressure goal.
- In the most cases, treatment of orthostatic hypotension begins with nonpharmacological interventions, including withdrawal of offending medications (when feasible), physical maneuvers, compression stockings, increased intake of salt and water, and regular exercise.
- If nonpharmacological measures fail to improve symptoms, pharmacologic agents should be initiated. Fludrocortisone, midodrine, nonsteroidal anti-inflammatory drugs, caffeine, and erythropoietin have all been used to treat orthostatic hypotension due to autonomic failure.

From Gupta V, Lipsitz L. Orthostatic hypotension in the elderly: diagnosis and treatment. *Am J Med.* 2007;120:841–847.

### *Immunologic System*

Significant alterations in immunocompetence occur with aging, involving both cellular and humoral immune functions (110,111). Although the total number of lymphocytes decreases by about 15% in older adults, this does not appear to contribute significantly to the marked decline in immunocompetence (112). There is a decline in lymphocyte proliferation in response to antigen stimulation in older adults, as well as a higher incidence of anergy (110). Age-related shifts have been observed in the regulatory activities of T cells (i.e., fewer T cells with suppressor or helper activity) and monocytes or macrophages.

Changes in humoral immunity with aging include increases in circulating autoantibodies and immune complexes, with decreased antibody production (110). The latter is characterized by an attenuated response to immunization, with difficulty maintaining specific serum antibody levels.

The increased susceptibility of the elderly to infection is a function of both these age-related changes in immune function and the frequency of concomitant factors that further impair host defenses (e.g., diabetes, malignancy, vascular disease, malnutrition, and stress) (110). Altered local barriers to infection, such as skin breakdown or an indwelling urinary catheter, often compromise resistance to infection further. Common infectious processes in the elderly include influenza, pneumonia, urinary tract infection, sepsis, herpes zoster, and postoperative wound infections.

Of particular clinical relevance is the fact that older people react differently to infections than do their younger counterparts. There is a less active leukocytosis in response to inflammation, and the total white blood cell count often is not increased (although usually there is still a shift of the differential count to the left) (113). The older patient may have less pain or other symptomatology, and frequently absent, or only low-grade, fever.

### *Endocrine System*

The endocrine system also undergoes significant changes as we grow older. There is a gradual decrease in glucose tolerance with aging, although the fasting blood sugar level remains relatively unchanged (56). Accordingly, age-adjusted criteria for diabetes mellitus have been developed. This age-related decline in glucose tolerance is due to reduced sensitivity of tissues to the metabolic effects of insulin or insulin resistance (114,115). Compounding these aging changes are secondary conditions that further reduce tissue sensitivity to insulin, including lifestyle changes (e.g., obesity, diet changes, stress, sedentary lifestyle), other diseases (e.g., chronic infections, prolonged immobilization), and effects of medications (45,116). Older adults with diabetes are also at increased risk for common geriatric syndromes (e.g., depression, falls) (117).

Of clinical importance is the risk for untreated hyperglycemia, osmotic diuresis, and dehydration, potentially leading to hyperosmolar nonketotic coma or ketoacidosis (116). Certain drugs can cause or potentiate hyperglycemia (e.g., thiazide diuretics, glucocorticoids, tricyclic antidepressants, phenothiazines, phenytoin) (118). Control of serum glucose in older

diabetics with oral sulfonylureas or insulin can be fragile, with significant risk for hypoglycemia. However, even borderline hyperglycemia appears to result in accelerated atherosclerosis and multiple end-organ involvement (56). On the other hand, recent data indicate that extremely tight glycemic control in type 2 diabetics may also be harmful (119). Of interest are the contributions of obesity and physical inactivity to the increased incidence of diabetes in older adults and the benefits of weight loss and regular exercise in improving control (45).

There are multiple other endocrine changes associated with aging. The primary clinical impact of altered thyroid physiology with aging is the need to maintain a high index of suspicion for the unusual presentation of thyroid disease (120). Presenting signs and symptoms of the older thyrotoxic patient may include palpitations, congestive heart failure, angina, atrial fibrillation, major weight loss associated with anorexia, and either diarrhea or constipation (121). Goiter and serious ophthalmopathy frequently are absent. Apathetic hyperthyroidism may not be recognized until late in the course of illness: patients appear depressed and withdrawn, with clinical clues of muscle weakness, dramatic weight loss, and cardiac dysfunction (116). Signs and symptoms of hypothyroidism essentially are unchanged with aging, but the diagnosis still may be delayed because of the many similarities between the stereotype of senescence and the hypothyroid state (e.g., psychomotor retardation, depression, constipation, cold intolerance). In view of the higher incidence of hypothyroidism in older adults, routine periodic screening of thyroid function is warranted (121).

The relationships among the hypothalamus, pituitary, and adrenal cortex remain unchanged with age, with preserved diurnal rhythm and stress response (116). However, in older women, serum cortisol concentrations vary more over the course of a day, and mean daily cortisol and ACTH (adrenocorticotrophic hormone)-stimulated serum cortisol levels are higher (122,123). Primary adrenocortical disease is uncommon in the elderly. Significant hyponatremia or hyperkalemia, suggestive of adrenocortical insufficiency, is not uncommon in the elderly but more often is secondary to drugs (e.g., thiazide diuretics, chlorpropamide, carbamazepine) (88).

Age-related changes in gonadal function are well documented. There are variable and gradual declines in serum testosterone levels in healthy men with aging, likely due to partial testicular failure; however, there is no indication for routine androgen replacement (56,124). Postmenopausal declines in estrogen levels are well documented, with clinical expression variably including vasomotor instability syndrome (i.e., hot flashes), atrophic vaginitis, and osteoporosis (43,125). Controversy continues over prophylaxis and treatment of the latter, particularly with regard to potential benefits of dietary supplements and exercise (43,45,126). The reader is referred to Chapter 39 for further details.

### *Thermoregulatory System*

Older people have only a mildly impaired temperature regulation system due to a combination of diminished sensitivity to temperature change and abnormal autonomic vasomotor

**FIGURE 59-3.** Thermoregulatory changes with aging.

control (127). As a result, they have a reduced ability to maintain body temperature with changes in environmental temperature and are vulnerable to both hypothermia and hyperthermia (56,94). The risk of hypothermia is compounded further by impaired thermogenesis (i.e., inefficient shivering), with potential aggravation by a variety of conditions (e.g., hypothyroidism, hypoglycemia, malnutrition) or medications (e.g., ethanol, barbiturates, phenothiazines, benzodiazepines, narcotics) (94). Conversely, diminished sweating (due to higher body temperature to initiate sweating and decreased sweat production) is a major contributing factor in heat exhaustion and heat stroke in hot conditions (Fig. 59–3). Hypohidrosis is aggravated by anticholinergics, phenothiazines, and antidepressants (88). Two thirds of deaths from heat stroke occur in people over 60 years of age, reflecting this impairment in regulatory systems. This has major implications for rehabilitation exercise programs, particularly when combined with a tendency for dehydration (65).

### Sensory System

Deterioration of vision is one of the most recognized sensory changes occurring with aging. The most common visual change with increasing age is a gradual loss of the ability to increase thickness and curvature of the lens to focus on near objects (i.e., presbyopia) and physiologic miosis (56). Cataract formation, with opacification of the lens, occurs to some degree in 95% of the 65-or-older population. The elderly are also at significantly higher risk for further disease-related visual decrements (e.g., glaucoma, macular degeneration, diabetic retinopathy) (128). The result of these various changes is a loss of visual acuity, decrease in lateral fields of vision, decline in both dark adaptation ability and speed of adaptation, and higher minimal threshold for light perception. These changes have obvious implications in relation to the higher incidence of falls in the elderly, particularly at night (129,130).

Gradual decline in hearing acuity (i.e., presbycusis) also is characteristic of aging, although again a number of treatable disorders can cause superimposed hearing loss (e.g., wax occluding the outer canal, cholesteatomas, acoustic neuromas). Older people most commonly manifest a conductive hearing loss, possibly due to increased stiffness of the basilar membrane or distortion of perceived sound with increase in threshold sensitivity, narrower range of audibility, abnormal loudness, and difficulty discriminating complex sounds (131). Continuing advances in hearing aid technology make remediation of such hearing deficits increasingly feasible (132). Early recognition and treatment of hearing impairments are particularly critical in the presence of cognitive deficits to avoid adverse sequelae of social isolation and development of paranoid ideations or frank psychiatric reactions (129).

### Neurologic System

Numerous changes in the functioning of the neurologic system have been noted with aging (133). Three important areas of dysfunction accompanying normal aging include declines in short-term memory, loss of speed of motor activities (with slowing in the rate of central information processing), and changes in posture, proprioception, and gait (56).

The major controversy over neurologic changes with aging concerns cognitive functioning. A significant proportion of the observed decline in fluid intelligence with aging appears to be related to a decrease in the rate of central information processing (134–136). There is progressive deterioration in performance after age 20 on timed motor or cognitive tasks, including abstraction tests (e.g., digit symbol substitution test), reaction time tasks, and other tests requiring speed in processing of new information. Although there are declines with aging in motor and sensory nerve conduction velocities and rate of muscle contraction, they account for only a fraction of these slowed responses (135).

Many aspects of learning and memory remain relatively intact during normal aging, including immediate or primary memory as measured by digit span recall, retrieval from long-term storage, storage and retrieval of overlearned material, and semantic memory (137). However, age-related impairments have been documented consistently in tasks involving episodic short-term memory and incidental learning (138). Examples include difficulties with free recall of long (i.e., supraspan) lists of digits or words and paired-associate and serial rate learning, for both visually and verbally presented material. What these investigations indicate is that older adults are capable of new learning, but at a slower rate (137).

Because much of rehabilitation involves learning, these findings have major implications for rehabilitation programming for elderly people with disabilities. This is particularly true in the context of superimposed cognitive deficits, given that intellectual ability is an important determinant of the effectiveness of a standard geriatric rehabilitation program (4).

A final area of neurological age-related physiologic changes involves posture, proprioception, and gait (139). Older people in general are noted to demonstrate progressive declines in coordination and balance, related in part to impaired proprioception (140). This may have significant implications for degree of mobility and stability, although there are a number of common, potentially concomitant, pathologic changes that may contribute further to gait problems in the elderly (e.g., vertebral compression fractures with kyphosis, arthritis, degenerative cerebral changes, cerebral infarcts) (130,141).

### ***Musculoskeletal System***

There is a well-documented progressive loss of muscle strength with aging, on the order of 14% to 16% per decade (men and women) for lower-extremity muscles and 2% (women) to 12% (men) per decade for upper-extremity muscles (59). A major contributing factor to this observed decline in strength appears to be an overall decrease in muscle cross-sectional area and mass with age (142). However, there may be significant contributions of cellular, neural, or metabolic factors to changes in strength, as loss of strength was observed even without loss of muscle mass (59). Further, significant gains in muscle strength, as well as functional mobility, have been demonstrated in older individuals with a structured, high-intensity resistance exercise program, even in frail nursing home residents up to 96 years of age (143).

The high prevalence of both osteoporosis and degenerative joint disease (i.e., osteoarthritis) in the elderly again raises the question about normal physiologic changes versus ubiquitous pathologic processes (45,144). The physiologic changes and sequelae associated with osteoporosis are discussed further in Chapter 39.

Distinction of the “disease” of osteoarthritis from the normal or usual aging changes that occur in weight-bearing joints can be made on a biochemical basis: with osteoarthritis, there are increases in the water content of cartilage and the ratio of chondroitin-4-sulfate to chondroitin-6-sulfate, with decreases in keratin sulfate and hyaluronic acid content (the opposite

of what occurs in aging) (144). There is a strong relationship between aging and osteoarthritis: Degenerative joint changes in weight-bearing joints are essentially a universal occurrence in both genders by 60 years of age (145). These changes include biochemical alteration of cartilage, especially the proteoglycan component, with reduced ability to bear weight without fissuring; focal fibrillation and ulceration of cartilage, and eventual exposure of the subchondral bone (144). The wear and tear hypothesis of osteoarthritis suggests that this process is the result of the cumulative stresses of a lifetime of joint use. Accordingly, “primary” osteoarthritis results from the stress of repetitive weight loading (e.g., spine, knees) or strain (e.g., distal interphalangeal joints), whereas “secondary” osteoarthritis may be related to occupational factors or congenital factors with unusual patterns of stress (e.g., congenital hip dysplasia). There appear to be other factors operating, however, because there are specific differences in distribution and prevalence between genders and races, and other explanatory models have been proposed (145–147). Obesity appears to be a risk factor for knee osteoarthritis in particular, although it is not clear whether this is due to a mechanical or a metabolic etiology. Further details regarding arthritis can be found in Chapter 31.

### ***Genitourinary System***

Benign prostatic hyperplasia is an almost universal occurrence in men older than 60 years of age and develops under hormonal rather than neoplastic influence (148). Of note is that the median lobe of the prostate, which is not palpable rectally, can cause a ball-valve obstruction during micturition. Accordingly, after ruling out other etiologies (e.g., anticholinergic or diuretic medication side effects), cystoscopy should be considered in patients with persisting obstructive symptomatology but minimal prostatic tissue on rectal examination to detect median lobe hypertrophy (149). Usual indications for surgical intervention (e.g., prostatectomy) include increasing obstructive symptoms, recurrent/persistent gross hematuria, bladder calculi, recurrent infections, and postvoid residual volumes greater than 100 mL (148,150).

Incontinence in the elderly, although increasingly prevalent with advancing age, should be regarded as a symptom of underlying disease; it does not result from the natural aging process (151). Normal aging typically results in decreases in bladder capacity, ability to postpone voiding, detrusor contractility, and urinary flow rate (152). Postvoid residual volumes are typically increased, with a tendency for increased urine output later in the day, as well as propensity for uninhibited detrusor contractions. Each of these changes predisposes older adults to incontinence, but none alone precipitates it. Common medical conditions associated with incontinence are listed in Table 59–3, while precipitating (and reversible) causes of transient incontinence are detailed in Table 59–4.

The primary clinical significance of these aging changes is that the new onset, or exacerbation, of incontinence in an older person is likely due to a precipitating factor outside the urinary tract (151). Usually, remedial intervention can restore continence.

**TABLE 59.3 Common Medical Conditions Associated with Incontinence in the Elderly**

Condition	Effect on Continence
Neurologic disease	
Cerebrovascular disease; stroke	DO from damage to upper motor neurons; impaired sensation to void from interruption of subcortical pathways; impaired function and cognition
Delirium	Impaired function and cognition
Dementia	DO from damage to upper motor neurons; impaired function and cognition
Multiple sclerosis	DO, areflexia, or sphincter dyssynergia (dependent on level of synergy)
Multisystem atrophy	Detrusor and sphincter areflexia from damage to spinal intermediolateral tracts
Normal-pressure hydrocephalus	DO from compression of frontal inhibitory centers; impaired function and cognition
Parkinson's disease	DO from loss of inhibitory centers; impaired function and cognition; retention and overflow from constipation
Spinal cord injury	DO, areflexia, or sphincter dyssynergia (dependent on level of injury)
Spinal stenosis	DO from damage to detrusor upper motor neurons (cervical stenosis); DO or areflexia (lumbar stenosis)
Metabolic disease	
Diabetes mellitus	Detrusor underactivity due to neuropathy, DO, osmotic diuresis; altered mental status from hyper- or hypoglycemia; retention and overflow from constipation
Hypercalcemia	Diuresis; altered mental status
Vitamin B <sub>12</sub> deficiency	Impaired bladder sensation and detrusor underactivity from peripheral neuropathy
Infectious disease	
Herpes zoster	Urinary retention if sacral dermatomes involved; outlet obstruction from viral prostatitis in men; retention and overflow UI from constipation
Human immunodeficiency virus	DO, areflexia, or sphincter dyssynergia
Neurosyphilis	DO, areflexia, or sphincter dyssynergia
Tuberculosis	Incontinence and functional impairments (sterile pyuria found in ≤50% of genitourinary TB cases)
Psychiatric disease	
Affective and anxiety disorders	Decreased motivation
Alcoholism	Functional and cognitive impairments; rapid diuresis and retention in acute intoxication
Psychosis	Functional and cognitive impairments; decreased motivation
Cardiovascular disease	
Arteriovascular disease	Detrusor underactivity or areflexia from ischemic myopathy or neuropathy
Congestive heart failure	Nocturnal diuresis
Other organ system diseases	
GI disease	Retention and overflow UI from constipation
Musculoskeletal disease	Mobility impairment; DO from cervical myelopathy in rheumatoid arthritis and osteoarthritis
Peripheral venous insufficiency	Nocturnal diuresis
Pulmonary disease	Exacerbation of stress UI by chronic cough

DO, detrusor overactivity; TB, tuberculosis; UI, urinary incontinence.

Adapted from DuBeau CE. Interpreting the effect of common medical conditions on voiding dysfunction in the elderly. *Urol Clin North Am.* 1996;23(1):11–18, with permission.

Contrary to stereotypes, although there is a decrease in sexual functioning with aging, most older people retain sexual interest and desire and to a variable extent, capability (153–155). Older men experience a decrease in ability to have psychogenic erections and require more intense physical stimulation for erection; erections may be partial, and orgasm with ejaculation may occur without full engorgement (156). The force of ejaculation is less, along with a less intense sensation of orgasm. Impotence may be caused by a variety of diseases (e.g., atherosclerosis, diabetes, hypothyroidism) and medications (e.g., antihypertensives, phenytoin, cimetidine). Treatment of erectile dysfunction in

older men has been revolutionized with development of the vacuum tumescent device, advances in penile prostheses, and availability of such medications as sildenafil and alprostadil (157,158).

Older women experience postmenopausal changes, including increased fragility of the vaginal wall and attenuation of the excitement phase (e.g., decreased vaginal lubrication) (153). Common sexual difficulties identified included partner's impotence, anorgasmia, decreased libido, and insufficient opportunities for sexual encounters. Despite these changes, most women maintain the ability to engage in sexual intercourse throughout the life cycle (159).

**TABLE 59.4** Precipitating Causes of Transient Incontinence in the Elderly

Cause	Comment
Delirium, confusion state	UI resolves once underlying cause(s) treated
Urinary infection	UI may be only symptom of infection; antibiotic trial warranted in asymptomatic persons only on initial evaluation and with new onset/exacerbation of UI
Atrophic urethritis, vaginitis	Aggravates stress or urge UI; agitation can be presenting symptom in demented patients
Medications	Any agent that impairs cognition, mobility, fluid balance, bladder contractility, or sphincter function; many agents impair several functions
Psychiatric disorders	Severe depression or psychosis
Increased urine output	Frequency or nocturia; causes: excessive fluid intake, diuretics, hyperglycemia, hypercalcemia, volume overload (congestive heart failure, venous insufficiency, hypothyroidism, hypoalbuminemia, and drug-induced peripheral edema)
Restricted mobility	Treat underlying cause; provide a urinal or bedside commode
Stool impaction	Urge or overflow UI; fecal incontinence common

UI, urinary incontinence.

## IMPACT OF THE ENVIRONMENT ON THE HEALTH OF OLDER ADULTS

### Psychological and Social Issues in Aging

#### Ageism and Myths of Aging

Butler coined the term “ageism” (or agism) to describe negatively biased perceptions of older people by the younger population in today’s youth-oriented culture, as well as perceptions of old age by elderly individuals themselves (160). There are many adverse sequelae of ageism, including devaluation of older people (by themselves, as well as others both younger and older), diversion of health care professional focus from the real health problems of older patients, the dearth of physicians interested and trained in geriatric medicine, and lack of curriculum time in medical schools regarding geriatrics (161–163). There is even new evidence of a negative impact of perceived discrimination on mortality in older adults (164). According to Rowe, it is time to “discard the many derogatory myths about older people, who are often seen as sick, senile, silly, sexless, and sedentary, as well as inflexible, irritable, noncontributing, and too old for preventive interventions” (165). Many of today’s older adults are survivors of the Depression and the World Wars—they built much of the life and standard of living we now enjoy. The evidence is clear: the majority of elderly are cognitively intact, live independently in the community, and are fully independent in ADL (17,19).

#### Cumulative Changes

There is increasing awareness of the critical interrelationships, particularly for older people, of physical health, mental health, and life circumstances. The emotional and life stress associated with major losses are well documented, and older people may be exposed progressively to multiple significant losses: job, income, health, functional ability and independence, parents, spouse, siblings, children, friends, social roles and status, and

self-esteem (166). There are in fact few norms or defined role expectations regarding appropriate behavior or activities in old age (167,168). Bereavement, isolation, poverty, illness, and physical disability all are associated with a higher incidence of depression in older adults (169), which in turn is associated with decreased physical and cognitive functioning, disability, and increased mortality (34,170–172).

#### Social Support Networks

Social support networks include a wide variety of sources that can be categorized as informal (family), semiformal (church, clubs, family doctor, local pharmacist), and formal (health care system, social service agencies, insurance companies, etc.) (173,174). Older persons often use supports from a combination of these networks (13). There is mounting evidence of the positive impact of social support networks on the cognitive, health, and functional statuses of older individuals (174–176).

Elderly people with children usually live near them and visit frequently or at least maintain regular telephone contact (177). Older people without children tend to maintain closer ties with young relatives or with siblings (178). It is important to consider the extended family, including cousins, in-laws, and others, with regard to support networks, rather than just immediate household members (167,174,179).

Institutionalization of an impaired older person usually is the last resort for families, used only when all other efforts fail; in fact, 64% of individuals over the age of 85 who are dependent in self-care or homemaking still live in the community (180). Families, rather than the formal system of government and agencies, provide the bulk (up to 90%) of personalized long-term care for their disabled older relatives (13). This includes home health and nursing care, personal care, household maintenance, transportation, cooking, and shopping. In 1990, 73% of elderly disabled individuals relied exclusively on such informal support and care networks (13).

With advancing age, however, older adults tend to have increasingly limited and relatively fragile support systems. Dependency in aging parents can result in significant physical, emotional, and financial stresses on their family network (177). An alternative support system may evolve gradually over a period of time as the older person loses family support (e.g., death of spouse and siblings, children moving away and unable to actively assist). Such a system might include friends and neighbors in an extended network to assist with shopping, cooking, cleaning, and self-care (174,181).

With whatever combination of support systems, a significant additional insult (e.g., onset of a new disease or complication) may overtax an already marginal arrangement. It is commonly observed that as the patient's dependence on the formal network of the health care system increases, the informal or family network support decreases (176). Furthermore, if the elderly person is hospitalized for a prolonged period, the network(s) may dissipate and may be difficult or impossible to reassemble (182). The critical importance of maintaining the integrity of support networks is illustrated by the observation that for every aged impaired person in a nursing home there are two equally impaired older people living in the community (3). The difference is the role played by the latter's informal support systems, providing most of their long-term care.

Increasingly, issues concerning family functioning with aging are being studied. Even when family members are seemingly available to assist older relatives, their support cannot always be counted on unless they too receive help. Fortunately, there is evidence that patients' families can benefit from educational interventions to help prevent weakening in this crucial source of patient support. Caregivers of older patients with cancer and chronic pain are often frustrated, fearful, and anxious. Patient care improved when caregivers were provided with guidelines on what they could do within the home to help the patient (176). Similarly, caregivers of stroke survivors had less depression and better outcomes with more formal training (183). Nursing home placement has been delayed by specific family interventions for patients with Alzheimer's disease (184).

Caregiver burden is another dynamic receiving increasing attention (185). Increased caregiver burden can be associated with increased mortality after controlling for known risk factors (186). Adding to the physical stress of providing personal care aid may be the unpleasantness of incontinence or exhaustion due to a relative's sleep disorder. Behavioral problems, such as agitation or impulsivity with poor safety awareness, create proportionately greater caregiver burden than the demands of providing physical assistance (185). Physical and emotional health problems among caregivers have been documented, including depression and immunosuppression. Physical aggression on a caregiver by a patient is not uncommon and may lead to reciprocal abuse (187). Potential intervention strategies include encouraging use of other support systems to augment care provided by family members, as well as the use of respite programs (188,189).

### Functional Impact

Physically impaired older people tend to become socially isolated, which can result in exacerbation of medical problems, functional deficits, and mental health problems (particularly depression) (34,171). Other factors contributing to a vicious cycle of depression, withdrawal, and functional decline may include the stress of multiple losses, malnutrition, chronic ill health, pain, and adverse drug effects that aggravate depression (172). Unfortunately, the environment too often fosters dependency. A classic illustration is the acute hospital setting, where the focus is on routinely providing care and assistance, rather than encouraging self-care (190,191).

Additional psychosocial barriers can interfere with maintaining or improving functional ability in the elderly. Handicapping sequelae of ageism include devaluation of elderly disabled (by themselves as well as others), lack of interest (actual and/or perceived) among health care professionals in their problems, and limited opportunity for access to appropriate rehabilitation services (161,165). Further attitudinal obstacles encountered among disabled elderly include the "right of dependency," perceived as earned by virtue of longevity, and the "apathy of fatigue," both physical and emotional, associated with multiple illnesses and hospitalizations (192).

Increasingly, physical environments are being recognized as either preventing or contributing to disability (193). While full discussion is beyond the scope of this chapter, the development of a requirement for some housing to meet visitability criteria (one entrance without stairs, bathroom on first floor, and wide bathroom doorway to accommodate a wheelchair) is encouraging. Housing adapted in this manner may more easily accommodate older adults as they age and facilitate social visits to or from friends by minimizing physical barriers.

The obvious conclusion, and why rehabilitation plays a key role in restoring function in disabled older people, is the importance of awareness and intervention regarding significant psychoemotional and social factors affecting their health. Many of these factors can be anticipated and prevented, or at least minimized in terms of their adverse effects. As with any complication, prevention is the best treatment.

### Cumulative Functional Sequelae of Disease

Older adults can experience acute onset of disability just as in younger people from such conditions as stroke, amputation, spinal cord injury (SCI), and traumatic brain injury. However, many experience a gradual progression of difficulties in function. The effects of multiple and chronic illnesses usually are gradual over time with cumulative erosion of organ reserves, leaving the elderly person reasonably functional with various adaptations, such as walking more slowly or taking more frequent rests (27,35,45). As functional problems develop, it can be hard to determine if the disability can be treated generically (i.e., regardless of the contributing diseases and other factors) or it is due to a reversible underlying disease process that needs to be treated. Also, an elderly individual may be only marginally functional with little or no reserve capacity, so that even a relatively minor superimposed acute

complication or disease process (e.g., influenza) may result in functional decompensation (3,194). Of even greater concern is that this significant functional decompensation may be difficult to reverse even though the intercurrent acute illness is appropriately treated and resolves (194–197).

### Underreporting of Illness

Older people as a group are more vulnerable to functional sequelae of diseases for a variety of reasons, including ageism. The latter commonly results in underreporting symptomatology related to illness (35,160). Health care providers may not be trained adequately to evaluate and treat symptoms and signs of functional disability in older patients and may as a result not recognize the significance of vague and inconsistent symptoms. Older people themselves may think that such vague symptoms are a natural result of aging (197). As a result, the underlying disease process may become quite advanced before care is sought, making treatment that much more difficult.

From the older person's viewpoint, the available system of care may seem unresponsive (35). Physician offices can be perceived as inconveniently located, with inadequate parking and limited access for the physically impaired. A typically brief physician encounter may not allow for development of rapport and full elaboration of symptoms. Busy office staff may appear to be uninterested or discourteous.

Other issues may contribute further to underreporting of illness. There may be denial of disease coupled with fear of consequences, especially financial (160). Depression is common among older people and may result in the attitude, "What have I got to gain?" (35,171). Increasing isolation, with fewer opportunities for others to observe and react to changes in appearance or behavior, is an additional barrier. Finally, older people may not recognize significant symptoms or seek medical attention because of cognitive impairments, which not infrequently may be secondary to or aggravated by an underlying and potentially reversible disease process (135).

### Altered Response to Illness

There is often an altered response to illness in the elderly, which contributes to a delayed, or incorrect, initial diagnosis (35). Many specific diseases present with atypical signs and symptoms. For example, the presentation of a myocardial infarction in an elderly person is less likely to include classic retrosternal chest pain; more often it will involve nausea, dizziness, syncope, or congestive heart failure with decreased activity tolerance (78). Furthermore, a wide variety of diseases may present with similar nonspecific symptoms, including confusion, weakness, weight loss, and general "failure to thrive" (35,198). Accordingly, the differential diagnosis of possible disease processes is much broader in elderly patients.

### Variable Patterns of Disease

Further confounding accurate elucidation of the underlying illness are the frequent changes in disease patterns and distribution (35). Abnormalities in one organ system may be accompanied by secondary abnormalities in other organ systems.

Traditional medical training focuses on disease recognition and treatment in a relatively young population, with emphasis on synthesizing multiple signs and symptoms into a single unifying diagnosis (35,199). Older people more typically have concurrent symptomatology, relating to multiple diseases. Although accurate diagnosis is important, the functional impact of each disease, particularly the cumulative and additive impact of multiple diseases, must be determined (3).

### Atypical Responses to Treatment

There is an increased frequency of many chronic diseases in this population, including anemia, osteoarthritis, osteoporosis, cardiovascular disease, malignancy, and malnutrition. Table 59-5 lists types and patterns of disabilities associated with various chronic conditions. Palliation and prevention of secondary complications frequently are more appropriate and realistic goals than is cure of the primary condition (35,199). There often are atypical (and potentially confusing) behaviors and responses to treatment, however, due to coexisting diseases and decreased functional reserves of multiple organ systems (e.g., affecting drug metabolism and distribution) (35).

Older people also are more prone to a wide variety of concomitant and complicating diseases, which may further cloud diagnosis and treatment decisions. Examples include thrombophlebitis, dehydration, fluid and electrolyte disturbances, adverse drug interactions or toxicity, pressure ulcers, pneumonia, and general deleterious effects of deconditioning due to inactivity, which occurs earlier and with greater severity in older adults (200,201).

Frailty as a concept refers to more than just older individuals who experience functional loss; it represents a state of vulnerability resulting from the balance and interplay of medical and social factors (38,39,202). Characteristics of frail older institutionalized persons included female gender, being unmarried, absence of a caregiver, presence of cognitive deficit, functional impairment, and medical condition (e.g., diabetes mellitus, stroke, Parkinson's disease) (203).

"Frailty" is becoming better characterized as a biologic syndrome of older adults associated with decreased reserve and resistance to stressors (38,39,204). Contributing are the multiple decrements in physiologic systems, as previously discussed. Clinical characteristics have been defined as unintentional weight loss (10 lb in prior year), self-reported exhaustion, weakness (decreased grip strength), slow walking speed, and decreased physical activity. Using these criteria, if three or more of these characteristics are present, the individual may be classified as frail (38,204).

### Models of Disease Presentation

Given these multiple dynamics, alternative models of disease presentation in older persons may prove useful (199). In one series of proposed models (Table 59-6), the most basic is the *Medical Model*, in which the patient's symptoms and signs are fully explained by one disease. The *Synergistic Morbidity Model* explains the functional loss that may have suddenly occurred as the result of the additive effects of several diseases. In the

*Attribution Model*, a patient might attribute a deterioration in health to an already diagnosed chronic illness when in fact another undiagnosed problem is present (e.g., hypothyroidism superimposed on stroke). In the more complex *Causal Chain Model*, a medical-psychiatric interaction occurs in which

one illness causes another in addition to causing functional decrements, with the presenting complaint representing the proverbial last straw of decompensation. Finally, in the *Unmasking Event Model*, a stressful external event unmasks an underlying, stable, or slowly progressive chronic condition

**TABLE 59.6** Alternative Models of Illness Presentation

Model of Illness	Characteristics
1. Medical Model	Symptoms and signs correlate directly (and solely) with a specific disease (traditional model of medical diagnostic thinking).
2. Synergistic Morbidity Model	Multiple concurrent chronic diseases, subclinical (or at least not severe enough to seek medical attention) until reaching a threshold of cumulative morbidity and functional decline.
3. Attribution Model	Underlying stable chronic disease(s), with new onset of symptoms attributed by the patient (and possibly, the clinician) to the known chronic disease(s), but in actuality caused by a new, unrecognized condition.
4. Causal Chain Model	Medical-psychiatric interaction involving an underlying disease with multiple secondary conditions/ impairments (potentially including mental health problems, such as depression), which aggravate the underlying disease, forming a “vicious cycle.”
5. Unmasking Event Model	Underlying stable or slowly progressive chronic disease(s), effectively compensated to minimize functional impact, until the occurrence of a new stressful event (e.g., death of a loved one, relocation), which results in decompensation (and the risk of being misinterpreted as a new condition).

Adapted from Fried LP, Storer DJ, King DE, et al. Diagnosis of illness presentation in the elderly. *J Am Geriatr Soc.* 1991;39:117–123.

that had previously been well compensated and unrecognized (199). Alternative classification models such as these help organize the significant and varying complexity of signs and symptoms, to more rapidly and accurately diagnose and treat older persons with multiple interacting problems.

### Effects of Acute Hospitalization

There is increasing recognition of the multiple deleterious effects of acute hospitalization on older people, separate and distinct from sequelae due primarily to their presenting illness (195,205). Disorientation due to the foreign hospital environment and relatively infrequent and brief interactions with unfamiliar health care personnel may contribute to bizarre and inappropriate behavior, including delirium and agitation (171,190,206). Contributing to this may be relative sensory and social isolation with few familiar environmental cues or social interactions, especially if the patient is confined to a private room or intensive care setting. Moreover, there are atypical routines and schedules (e.g., blood drawing, vital sign checks at odd hours), which, coupled with unusual noises (e.g., overhead paging, machines, other patients), may contribute to insomnia. A patient with insomnia typically is treated with a sedative medication, which may begin a cycle (or cascade) of drug side effects and interactions that may adversely affect the patient's health (195,205).

Increased incidence of medical and iatrogenic complications in older adults is well documented (35,199). Drug side effects, complications, and toxicity, together with adverse interactions related to polypharmacy, make up a large proportion of such morbidity (35,81). There also is a greater frequency of diagnostic and therapeutic misadventures in this age group, related in part to decreased organ reserve with resultant increased vulnerability (205).

There also are a variety of emotional sequelae of hospitalization that may affect health and functional statuses. Anxiety and confusion relating to the underlying illness and prognosis, or just to hospitalization itself, may interfere with cooperation with medical treatment or therapy programs (207–209). Depression from similar origins may result in dependency and poor motivation to cooperate or improve function (170,171). Functional dependency frequently is reinforced during acute hospitalizations, both by the older patients who expect hospital staff to assist and by hospital staff who tend routinely to perform self-care tasks without taking the extra time to supervise the patient in performing his or her own self-care (192,195). Documented functional decline after hospitalization for acute medical illnesses also may result from other, as yet unexplained, factors (205). Deconditioning from inadequate activity during the hospital stay may contribute to poorer functional outcomes, and a recent study indicates that older adults are more sensitive to the deleterious effects of bed rest as compared to younger individuals (210). Preliminary results are mixed as to whether exercise during hospitalization can help improve functional outcomes (211,212).

In addition to significant implications for health care in the hospital setting, these sequelae related to acute hospitalization

often affect social support systems and discharge disposition (182,195). The elderly patient may experience loss of confidence or motivation as a result of multiple insults and complications, coupled with erosion of functional abilities from deconditioning (200,201). This by itself will put greater stress on often relatively fragile social support systems, making it more difficult for elderly patients to return home to their prior living situation (182).

To try to address these problems, several randomized trials have investigated alternative models attempting to change the organization of care (and outcomes) for older persons during hospitalization. Use of a geriatric consultation team approach did not yield improved outcomes (213). In another randomized clinical trial of 651 patients 70 years of age and older, the experimental patients received care on a special unit, which had the additional components of daily team conferences, active discharge planning, and use of therapy staff for functional training—the core components of an acute rehabilitation unit. Patients in the experimental group were discharged at higher functional levels, and fewer were discharged to skilled nursing facilities (14% vs. 22%). Neither cost of hospitalization nor length of stay was increased (214). In a Veterans Administration study, older patients, after stabilization, were randomized to usual care or to a geriatric rehabilitation unit (215). At hospital discharge, patients receiving the geriatric unit care had greater improvements in scores for four of the eight SF-36 subscales, ADL, and physical performance. These studies suggest potential strategies to improve acute hospital care for older persons, with less functional sequelae. Unfortunately, similar programs have not been routinely implemented despite their demonstrated benefit (216).

### Effects of Deconditioning

Deconditioning can be defined as the multiple changes in physiology and anatomy induced by physical inactivity and reversed through physical activity (201). This topic is covered in detail in Chapter 48, but will be discussed here relative to unique aspects relating to aging.

Older adults' (75 to 120 years old) physical functioning and associated physical activities have been classified by Spirduso into five categories: physically elite, physically fit, physically independent, physically frail, and physically dependent (217) (Fig. 59–4). Deconditioning can be one component, in addition to disease, that may contribute to a patient's lower level of function. In addition, low fitness is an important predictor of cardiovascular and all-cause mortality in older adults (218).

As noted before, older adults have a more substantial loss of muscle mass than younger adults with bed rest inactivity (210). However, the associated declines in lower-extremity strength and maximal aerobic capacity in these older subjects were similar to that reported in younger adults exposed to similar periods of bed rest. Reversal of the deleterious effects of deconditioning has been amply demonstrated through focused muscle-strengthening programs as well as comprehensive exercise programs in both nursing homes and the community

FITNESS LEVEL	Physically Elite *High risk & power sports *Senior Olympics	Physically Fit *Moderate physical work *Endurance sports *Most hobbies	Physically Independent *Very light physical work *Low physical demand activities (e.g., golf, driving) *All IADLs	Physically Frail *Light housekeeping *Some IADLs *All ADLs *May be homebound	Physically Dependent *No or only some ADLs *Needs home-based or institutional care
	Leisure Activity Levels/Functional Levels				

**FIGURE 59-4.** Hierarchy of physical function of the old (75 to 85 years) and oldest old (86 to 120 years). (Adapted from Spirduso W. *Physical Dimensions of Aging*. Champaign, IL: Human Kinetics; 1995:1–432.)

(67,219–221). These programs variably included exercises for flexibility, muscle strength, and aerobic endurance.

The functional consequences of deconditioning in older people may be of major clinical significance and may be confused with changes intrinsic to aging or changes from diseases (201). In addition to deconditioning, sarcopenia is another process that can affect overall function in older individuals (222). Deconditioning *per se* may result in functional losses when certain threshold values for physical performance are crossed (223). Quadriceps weakness may progress to the point of dependency in getting in and out of a car solely from progressive deconditioning, not related to intrinsic aging or new onset of disease (200). Multiple factors associated with falls may originate from deconditioning, or be exacerbated by deconditioning (224,225). For people living in the community, factors associated with falls include impairments in static balance, leg strength, and hip and ankle flexibility (226,227). In nursing home patients, falls are associated with decreased muscle strength at the knees and ankles (228,229). Weakened muscles also may contribute to other injuries and pain syndromes by allowing abnormal forces to act on bone, joints, ligaments, and tendons. In addition, lack of exercise is being viewed increasingly as a risk factor not only for functional loss but also for onset of various disease processes, including cardiovascular disease and diabetes, among others (230).

Deconditioning affecting older people can be differentiated into acute inactivity secondary to bed rest (such as during acute illness) and chronic inactivity from sedentary lifestyles (often more difficult to reverse) (201). A variety of types and combinations of exercises are available to treat deconditioning in older individuals; a precise prescription of a therapeutic exercise and activity program, including appropriate precautions and instruction, is essential (65,107,231,232).

Psychological issues in maintaining exercise habits are being studied increasingly (219). Currently, health professionals

can help older persons increase their physical activity levels by discussing the issue openly and then helping the patient decide what approach may be most appropriate (103). One option may be group classes, which offer the benefits of social interaction and support, and perhaps even friendly competition. Exercising on their own at home may be preferable for some, especially if they are self-conscious about their own abilities (233).

### Disability Prevention in Older Adults

The future impact of increased disability as the population ages is of major concern to clinicians, health care administrators, insurers, and policy makers. Increasingly, prevention strategies are being proposed both to improve the number of disability-free years of life as well as to contain health care costs (16,19,28,31,34,36,38). Some of the themes around prevention can be organized according to the concepts of primary, secondary, and tertiary preventions. Primary prevention involves preventing the onset of a disease (e.g., annual influenza vaccine), whereas secondary prevention involves the diagnosis and treatment of asymptomatic diseases to prevent the development of symptoms (e.g., treatment of hypertension to prevent stroke or myocardial infarction). Tertiary prevention involves treatment once a disease becomes symptomatic to avoid complications (e.g., deep venous thrombosis prophylaxis and appropriate mobilization to prevent skin breakdown in poststroke patients). However, as previously discussed, what becomes increasingly important in older persons with chronic disease (*comorbidity*) is focused attention to preventing or minimizing *frailty* and, therefore, decreasing risk of development of *disability* (38).

Another model that may help in the development of prevention strategies has been proposed by Lawrence and Jette (234). They have studied the application of a model for the disablement process in 1,048 community-residing adults (mean age 74 years) without functional limitations or disabilities over

a 6-year period. The model hypothesized a process in which risk factors (age, gender, education, body mass, and physical activity measured as frequency of walking one mile) would lead to functional limitations with or without the presence of pathology or impairments. Over time, the functional limitations (e.g., inability to walk well) would lead to subsequent disability such as inability to go shopping. Guralnik et al. likewise found that among nondisabled persons living in the community, impairments in the lower extremity were highly predictive of later disability (235). Fried et al. characterized a functional level of “preclinical disability” (task modification but no difficulty by self-report) in a study of women 70 to 80 years old (236). Measurement of their physical function was intermediate between women with high function (no modifications) and disability (difficulty with tasks). The potential role of interventions involving increased physical activity and exercise as types of primary prevention of disability for older persons is supported by studies documenting the dynamic nature of functional loss and impact on both morbidity and mortality (37,38,40).

There may in fact be significant overlap of risk factors for multiple problems in older persons. For instance, the risk factors associated with falls, incontinence, and functional dependence are similar—slowed chair stand, decreased arm strength, decreased vision and hearing, and either a high anxiety or depression score (237).

From these types of models, successful prevention strategies are being tested, often entailing multiple interventions covering multiple domains. For instance, incidence of falls can be reduced by a combination of medication adjustments, exercise, safety training, and environmental modifications. A comprehensive nurse-practitioner evaluation program for community-residing seniors resulted in a delay in onset of disability and decreased nursing home admission (238). Another study demonstrated that higher self-efficacy was associated with lesser functional decline in persons with diminished physical capacity (239). Research also suggests that self-efficacy (i.e., a person's confidence or belief that he or she can achieve a specific behavior or cognitive state) may be modifiable and therefore help guide preventive strategies (240). Research continues to identify which targeted intervention for which specific risk factor in which specific patient at what specific point in time will be most efficacious in preventing or minimizing disability (38).

## PRINCIPLES OF ASSESSMENT AND REHABILITATIVE MANAGEMENT OF OLDER ADULTS WITH DISABILITY

### Assessment of the Older Patient

Rehabilitation medicine and geriatric medicine share common principals and have complementary approaches (241). This is seen in patient assessments. Rehabilitation of older adults requires attention to multiple areas. Benefits of organized, comprehensive assessments and care have been documented for acute onset disabilities like stroke and are described elsewhere in this textbook. Assessments of older patients with more

insidious onset of multiple disabilities are evolving. They are collectively referred to as comprehensive geriatric assessment (CGA). Pioneering work by Dr. Marjorie Warren in Britain laid the foundation for CGA while evaluating many institutionalized older adults (242). The process was formally defined in the United States in a National Institute Consensus Development Conference in 1988 (243). CGA is “a multidisciplinary evaluation in which the multiple problems of older persons are uncovered, described, and explained, if possible, and in which the resources and strengths of the person are catalogued, need for services assessed, and a coordinated care plan developed to focus interventions of the person's problems” (243).

Since that time, numerous studies have evaluated CGA programs in different sites of care. While the majority focuses on the general medical geriatric population, a growing literature examines benefits in specific areas like oncology. CGA programs vary depending on the clinical setting and program design. A general conclusion from this work is that there can be benefits depending on patients targeted and the nature of the program. Targeting aims to identify older adults who are not terminal and who have multiple conditions. These patients also have associated disabilities amenable to known multifactorial interventions. Usually, beneficial programs include actual control of care provided rather than consultation alone.

Benefits for some, but not all, inpatient programs have included shorter lengths of stay, better management of specific syndromes, delays in functional decline, decreased bodily pain at 1 year, decreased need for home health care services, and higher likelihood of living at home in 6 months (242,244,245). In some recent studies, mortality at 1 year has not been changed. Some, but not all, outpatient CGA programs have shown delays in functional decline, improved mental health at 1 year, and earlier diagnosis of common health problems like cognitive impairment, depression and anxiety, and incontinence (245–248).

CGA topics are similar to what needs to be assessed during comprehensive rehabilitation. Issues include sensory, cognitive, emotional, functional, social, financial, legal, and home issues. Other commonalities are screening and evaluation of syndromes like incontinence and falls. These syndromes are common entities that result from multiple diseases and multiple risk factors (237,249).

A standardized framework for assessing older patients, and managing care, can facilitate both rehabilitation and follow-up care by other providers. With so many types of issues requiring assessment, and follow-up, a practical standard framework would help avoid oversight of relevant factors. Communication among team members would be easier. This is especially important because older adults receive care from multiple providers in multiple settings. One estimate suggests Medicare patients receive annually, on average, care from five specialists and two primary care providers in four different practice sites (250). Another estimate for stroke survivors is that they can receive care from up to 89 providers distributed among eight different health care teams in seven different locations (251).

The Siebens Domain Management Model (SDMM) is one practical clinical framework for organizing care for older

### The Siebens Domain Management Model

Clinical Problems	Time Line for Recovery/Health Maintenance

adults (Fig. 59–5). Four domains cover the spectrum of patient strengths as well as the clinical problems they face: Domain I—Medical/Surgical Issues, Domain II—Mental Status/Emotions/Coping, Domain III—Physical Function, and Domain IV—Living Environment (252). While sometimes patients have an isolated problem in one area, often assessment and management require actions in all four domains (253). These four domains apply to care in any treatment setting.

The SDMM is consistent with two theoretical models—the biopsychosocial model and the broader biopsychosocial-ecological model of Health Environmental Integration (254–256). The latter model includes patients' physical environments, in addition to their social environments. Both of these areas contribute to health and to disabilities. The SDMM is also consistent with the International Classification of Functioning, Disability, and Health in which contextual personal factors and environmental factors are considered alongside body structures, body functions, activities, and participation (193).

*Domain I (Medical/Surgical Issues)* in the SDMM includes the salient symptoms and disease diagnoses requiring management (e.g., diabetes, hypertension, osteoarthritis, or stroke). For older patients, various clinical syndromes also require explicit identification and management (e.g., incontinence, malnutrition). Elements of disease prevention are dimensions in Domain I as well.

*Domain II (Mental Status/Emotions/Coping)* identifies patients' strengths as well as any concerns with their mental status or cognitive function. These would include, for

example, issues of attention, memory, and executive function or complex problem solving. Delirium and dementia, with their diagnostic workups, are especially important to identify, if present, given their major impact on patients' functional status and rehabilitation management. Key emotional problems to identify include depression and anxiety disorders. Coping represents patients' ways of behaving when confronted with stressors of ill health. Many patients cope well. Their strengths can be noted. For patients who are having difficulty coping, additional assessment and help from the rehabilitation team are required. Spirituality is a key factor for many older patients confronting disability and can be a source of strength. Patient preferences are another dimension within this domain. One example is advance directives like health care proxy designations and medical directives. Assessment of Domain II depends especially on the ability of clinicians and patients to communicate effectively. Therefore, any communication difficulties are included in this domain. Examples are visual and hearing problems as well as aphasia or dysarthria.

*Domain III (Physical Function)* includes the full spectrum of functional activities performed by the patient. These range from basic ADLs (dressing, toileting, etc.) to instrumental or intermediate ADLs (shopping, transportation, money management, medication management, etc.) to the advanced ADLs (social, vocational, and avocational activities as well as fulfilling social roles like parenting).

*Domain IV (Living Environment)* includes three practical components: physical, social, and financial/community

resources. The patients' physical environment includes man-made structures as well as the natural world (257). Specific details include the type of housing and job site, building access, and proximity of basic necessities like food and banking services. For older persons with progressive disabilities, transitioning to more supportive home environments may be a critical goal in their care.

Patients' social environment is their interface with other people at many levels of association, ranging from social networks to social institutions (257). These interactions determine whether or not personal physical help or assistance with instrumental or advanced ADL is available. Caregiving by family and friends can be a rewarding experience. On the other hand, sometimes caregivers face significant burdens. Assessing caregivers' experiences, and assisting through education and supports when necessary, is an integral part of rehabilitation management (258).

Finally, financial and community resources are critical to determining what medical and rehabilitation services are available as well as what personal financial resources patients and their families may have. This can facilitate determination of what medications, services, and additional equipment are feasible as part of the rehabilitation program.

Practical applications of the SDMM include structuring of physicians' decision making in their documentation of their assessments/plans (252). Other applications include using it as a structure for team and family conferences, for teaching rehabilitation in residency programs, for medical student teaching about the care of older adults, and for efficient geriatric assessments in sites like emergency departments (259–263).

### Rehabilitation Goal Setting

Increasingly, there is recognition that health care and rehabilitation goals may not be uniformly shared by patients and their caregivers (264,265). For example, patients may want to return home after rehabilitation, while rehabilitation staff may strongly disagree, at times, out of undue fear of what may occur (266). Our focus as health care providers is typically on general health and well-being, as well as functional independence. Our tacit assumption is that these goals are necessarily shared by our patients and their caregivers and perhaps that these are the only goals they value. However, there is evidence of differing goals, and priorities of goals, between health care providers, case managers, patients, and their caregivers (264,265,267). Alternative goals also valued by patients and their caregivers included such areas as education and referrals, social/family relations, emotional issues, and caregiver burden. Of significance is that patients and family caregivers often focus on process goals and shorter time frames, as opposed to typical health care providers' emphasis on specific outcomes and longer range time frames (265).

### Prescription of Rehabilitation Programs

An appropriate therapeutic prescription is critical to the success of a rehabilitation program. It must be based on a careful

analysis of the patient's current functional limitations, with realistic goal setting in the context of premorbid functioning and anticipated improvement in medical status (268). Specific therapy techniques will be used based on physical status (e.g., neurologic, musculoskeletal, cardiovascular systems) and medical stability. Social and cultural barriers to certain exercises or activities also must be taken into account. The patient should participate in goal setting, such that the rehabilitation plan is relevant to his or her own goals. Without a strong therapeutic alliance between all health professional team members and the patient (and family), progress will be slow and/or limited.

Functional training approaches usually are well accepted by most older individuals because they can clearly see the relevance and importance. Many therapeutic goals can be achieved by incorporating formal therapy techniques into the context of functional tasks. Examples of this approach include the following techniques:

- Remediate perceptual problems during eating or meal preparation
- Increase range of motion with dressing training
- Strengthen through inclined sanding or woodworking projects
- Aerobic conditioning through adapted competitive sports.

Prescription of the rehabilitation program must be tailored to the person to accommodate limitations imposed by comorbid medical problems (65,100,107). Cardiovascular (e.g., blood pressure/pulse response, cardiac symptomatology) and pulmonary (e.g., use of oxygen) restrictions should be established as appropriate. Weight-bearing limits can be accommodated by means of assistive devices or aquatic therapy. In patients with limited exercise tolerance, it may be necessary to use flexibility with therapy scheduling and duration of treatment, with frequent rest periods. A number of authors have suggested practical rehabilitation guidelines that summarize these recommendations (107,269–271). Resnick proposes a seven-step model to help motivate older individuals to exercise, including education, goal setting, role modeling, and verbal encouragement/rewards (272).

Realistic goal setting is complex in any rehabilitation setting but may be complicated further in older patients in two unique respects. First, older adults frequently have potential caregivers (e.g., spouse, siblings, children) who also are aging and have medical problems of their own. Thus, the fitness and capability of the proposed caregiver after discharge must be considered in the discharge planning process (178,179,182). The second problem relates to the limited remaining life expectancy of the older disabled patient. For example, diabetic amputees over 65 years of age have average survival of approximately a year (273). In view of their potentially limited longevity, an expedited rehabilitation program to facilitate return home with family would be most appropriate. This would also apply to people with conditions that are progressively disabling and require increasingly frequent episodes of hospitalization and/or skilled nursing care.

A number of potentially negative or counterproductive team dynamics can develop in rehabilitation settings that may interfere with or limit a patient's progress (274,275). Patients and families tend to trust their health care providers as the experts who will know and do what is best for them. It is critical that the rehabilitation team maintain vigilance for and strive to counter such negative attitudes as paternalism (e.g., overriding patient goals judged by the team to be unrealistic or inappropriate), arrogance (e.g., presumptive familiarity by addressing patients by their first name without requesting permission or preference), and self-fulfilling prophecies (e.g., patients judged not to have potential for improvement not receiving as much attention or effort as patients felt to have a good prognosis). Other team issues that can impact effectiveness include relative team member roles (e.g., lack of clarity or excess rigidity), communication barriers, or decision-making conflicts (274). The ongoing challenge for rehabilitation teams is to foster an individual and collective philosophy of respect for and empowerment of the individuals they treat, facilitating functional independence. The latter includes (appropriate) risk taking (referred to as "dignity of risk").

### Significance of Functional Status in Placement Issues

Reference already has been made to the critical nature of functional status with regard to the ability to live independently in the community. Older people often live alone and must perform their own self-care and other daily activities, including homemaking. Issues of safety in this home environment frequently are raised, particularly after an acute adverse event or illness (e.g., a fall with hip fracture). A patient who achieves a level of mobility (i.e., ambulation or transfers) requiring only close supervision or contact guard assistance because of an occasional loss of balance may not be able to safely return home alone. Home-based supervision by an aide, unless paid privately, typically is available only a few hours a day, 5 days a week, for relatively limited intervals. In this instance, return to a community setting may only be possible if a relative is available to live with this individual. If not, he or she may not even qualify for a boarding home or intermediate care/assisted living facility; most intermediate care facility admission criteria include independent safe locomotion. This patient accordingly may require a skilled nursing facility (SNF, or nursing home) admission as the only source of 24-hour/day supervision available. Unfortunately, alternatives are limited for more homelike settings with other residents of similar functional level.

### Health Care Policy Issues

There is increasing evidence that health care financing can have a significant (if unintended) impact on the structure, delivery, and outcomes of health care. Chan et al. have analyzed the effect of changes in the Medicare payment system for rehabilitation hospitals on length of stay and charges, as well as discharge destinations (276–278). Their analyses

reveal that lengths of stay and charges dropped significantly the year after implementation of the new Medicare prospective payment system for rehabilitation, compared to the base year, for all diagnostic categories (276). A further dynamic involved an increased likelihood of discharge from a rehabilitation hospital to an SNF, particularly for (often older) patients with longer lengths of stay, under the new prospective payment system with its fixed reimbursement cap (277).

Chan et al. have also documented associations between type of insurance (Medicaid, health maintenance organizations (HMOs), commercial fee-for-service plans) and relative frequency of postacute hospital discharge settings (SNF vs. rehabilitation hospital) for patients with traumatic brain injury (279). Discharge from acute care hospitals to SNFs was significantly more likely for patients with Medicaid, and to a lesser extent with HMO coverage, than for patients with fee-for-service commercial insurance.

On the other hand, there is also evidence that programs specifically designed to improve quality of care for older patients can effect changes in health care delivery and outcomes. Coleman, on behalf of the HMO Care Management Workgroup, describes an evidence-based approach to improving quality of geriatric care within managed care organizations (280). Their premise is that by expanding the managed care organization focus to include older members at risk for functional decline and subsequent frail health (with higher health care costs), "upstream" approaches to maintain or improve functional reserve will result not only in improved health but also lower health care costs. There is clear evidence to support the premise of the correlation between activity limitation and increased health care costs (281).

Jencks et al. cite improvement in care rendered to Medicare patients over a 2-year interval, based on tracking of (and possibly related to feedback for) a number of quality of care indicators by the Quality Improvement Organization (QIO) program of the Centers for Medicare and Medicaid Services (CMS) (282). The quality indicators included inpatient management of acute myocardial infarction, heart failure, stroke, and pneumonia, as well as ambulatory preventive measures for breast cancer, diabetes, and pneumonia. Despite the historical shortcomings of quality improvement efforts on a national level as documented in *Healthy People 2010* (283), Jencks is optimistic that improvement in health care quality is not only possible but is occurring. He notes this trend should be reinforced by alignment of quality indicator tracking between such national agencies as CMS, the Joint Commission, and the National Quality Forum.

Along similar lines, Calkins et al. propose changes in components of the health care system to improve the health of older people, such as more detailed emergency room evaluations and more focused (and sustained) home health care services (284). What is clear in any case is that health care policy continues to be in flux, trying to address the challenges of financing and delivering appropriate care to older persons (278).

## REHABILITATION APPROACHES TO COMORBIDITY AND GERIATRIC SYNDROMES

### Medical Issues

#### Reassessment of Medical Status

Transfer of a patient from an acute medical or surgical service to a rehabilitation unit has been identified as an opportunity for a fresh and objective reassessment of medical status (285). Such an appraisal is even more critical in geriatric rehabilitation and should include confirming the accuracy of referral diagnoses, evaluating for previously unrecognized conditions, and reviewing medications for continuing appropriateness (199). Often an elderly patient's physiologic status has markedly improved or stabilized by the time of transfer, warranting consideration of altering dosage or discontinuing certain medications. Creating and using tools like a patient care notebook with medication lists is one process that can help clarify medication use (286). Patients can be encouraged to take these notebooks to all health care appointments.

#### Avoiding Adverse Drug Effects

The incidence of adverse drug reactions approaches 25% in people older than 80 years of age (35). Adverse drug reactions account for 11% to 20% of hospitalizations in people older than 65 years of age and are a frequent cause of mental deterioration (287–289). The reasons for drug problems in older adults revolve around five key interrelated areas:

1. Polypharmacy
2. Medications not taken as prescribed
3. Increased susceptibility to adverse reactions
4. Altered pharmacokinetics
5. Altered receptor sensitivity

#### *Polypharmacy*

Polypharmacy is frequent in older people and often compounded by the frequent use of nonprescription drugs, resulting in preventable adverse drug reactions and unnecessary financial costs (290,291). Physicians all too often contribute to this problem; one study found that one in five older patients received a prescription for a potentially inappropriate medication (292). Frequently, known risk factors are not taken into account when prescribing a particular medication and dosage (293,294). Medication histories obtained by physicians often are inaccurate in both inpatient and outpatient settings (295,296), related in part to lack of questioning and underreporting of over-the-counter (OTC) medications, which are used almost as frequently as prescription medications by older adults (297,298). Over 50% of OTC medications are oral analgesics, with the remainder consisting of cough-and-cold preparations, vitamins, antacids, and laxatives (296,298).

The hospital setting is an excellent opportunity to discontinue drugs of questionable value because careful monitoring is possible. Accordingly, all medications should be reviewed carefully on admission to a rehabilitation unit and regularly

thereafter. In addition to OTC medications, special attention should be directed to digitalis preparations, NSAIDs, and psychotropic medications (299).

In addition to unawareness of concurrent medications, other factors have been identified as potentially influencing prescribing habits and contributing to polypharmacy in older people. These include pharmaceutical advertising (particularly involving new drugs inadequately tested in older people) and patient and family expectations (or even demands) for treatment, usually in the form of a prescription (300). In one nursing home study, treatments (i.e., medication prescriptions) occurred more often if a patient's problem produced ongoing discomfort for the staff (e.g., agitation); conditions tended to be undertreated if symptoms were intermittent or had less impact on staff (e.g., arthritis) (301).

#### *Medications Not Taken as Prescribed*

Patients do not take medications as prescribed in one third to one half of all cases (302). Patients over 75 years of age who live alone are especially likely to not take medications as prescribed (296,298). Reasons given by patients in one study for not taking medications included "feeling the prescribed dosage was too high" and experiencing problematic side effects (303). These patient choices can cause postdischarge deterioration; patient education prior to discharge is critical to avoid such problems. Allowing patients to self-medicate in the hospital with flexible administration times may be a useful way to monitor their understanding and an opportunity to reinforce the need for medications (304). This strategy also may help to decrease the frequency of incorrect drug frequency or dosage, omitted medications, and use of expired medications (305). However, challenges remain in determining the best methods for enhancing patient adherence to medication prescriptions (306).

Drug toxicity can result when a patient is admitted to the hospital and given all the drugs (in the "correct" dosages and frequency) that have been previously prescribed but were not being taken at home. Such a problem should be suspected when a patient shows a decline in cognitive or functional status 5 to 10 days after admission and other medical workup is unrevealing (307).

#### *Increased Susceptibility to Adverse Reactions*

Adverse drug reactions appear to be more common in older patients, even when medications are given in the proper dosages (308). This may be related to a relative lack of resiliency in their homeostatic mechanisms (35,299). Although not all adverse drug reactions are avoidable, some investigators suggest that 70% to 90% could be anticipated and prevented (291,301,302). That some patients choose not to adhere to prescriptions given by physicians may in fact help decrease the frequency of adverse drug reactions (303). Serious side effects can occur secondary to OTC medications, especially from antihistamines with anticholinergic side effects, leading to fatigue and confusion even in middle-aged adults (297).

### ***Altered Pharmacokinetics***

There are a number of age-related changes in pharmacokinetics (see Chapter 65) with significant implications for drug dosing, timing of dosage changes, and potential for unexpected toxicity or interactions. The reader is referred to the previous discussion of organ system aging for hematologic, GI, hepatic, and renal systems.

### ***Altered Receptor Sensitivity***

Age-related changes in receptor sensitivity to drug effects are an additional reason for untoward drug effects in older people. There is evidence, for example, that benzodiazepines and warfarin have a greater effect at similar concentrations in the young compared with the elderly (300,308). Such changes are difficult to evaluate separately from the pharmacokinetic changes related to aging.

The common philosophy of “go low, go slow” is sound advice when prescribing drugs for older people. Evaluation of response to drug therapy is critical, and elimination of unnecessary medication is essential for improving function. Patient and family education as to the indications, contraindications, and adverse effects of drugs are even more important in older individuals to try to improve adherence and avoid adverse reactions (304,305).

### ***Hypotension***

Symptomatic orthostatic hypotension can occur in many older patients after even relatively short periods of bed rest (201,309). Orthostatic hypotension is defined as a decline of 20 mm Hg or more in systolic blood pressure when rising from supine to standing, usually accompanied by symptoms of dizziness or light-headedness (310). It is accordingly a frequent problem during early remobilization of elderly patients in rehabilitation settings. Symptoms can persist if there are underlying problems with blood pressure maintenance related to drug therapy, salt restriction, or autonomic dysfunction (78).

Evaluation of the orthostatic patient should include a review of medications (particularly nitrates, antihypertensives, levodopa, diuretics, phenothiazines, and tricyclic antidepressants), examination for autonomic dysfunction (e.g., pupillary response, abnormal sweating) or recent fluid loss, and laboratory tests to rule out abnormalities in aldosterone and cortisol levels (199,310,311). Metanephrines should be evaluated when hypotension occurs with episodic hypertension, a hallmark of pheochromocytoma (311).

Treatment for symptomatic orthostasis includes discontinuing any prescribed or OTC medication that could be contributing to the hypotension. The patient should be instructed to exercise (i.e., ankle dorsiflexion/plantar flexion) before arising, to sit up initially, and then to stand up slowly while holding onto a support. Thigh-high elastic stockings or an abdominal binder may help minimize lower-extremity blood pooling (310) (see Table 59-2). High-sodium diet and fludrocortisone acetate, a synthetic mineralocorticoid, are useful for plasma expansion in the absence of congestive heart failure. Other medications

to consider include NSAIDs (inhibit prostaglandin synthesis), clonidine or midodrine ( $\alpha$ 2-adrenergic agonists), propranolol (blocks  $\beta$ -2 vasodilatory receptors), pindolol (a  $\beta$ -adrenergic antagonist with intrinsic sympathomimetic activity), or phenylpropanolamine (a sympathomimetic) (299,300,310).

### **Significance of Mental and Emotional Status**

#### **Depression**

Depressed mood is a significant problem in older persons and is often missed. Given the importance of improving recognition of depression, several recent reviews have covered the topic in detail (312–315). Rates of major depression vary from 16% to 30% for elderly clinical populations, and prevalence rates in community-dwelling older persons range from 2% to 5%. The risk of depression has been estimated to be threefold greater for older persons with disability, compared to their functionally independent counterparts (170,316). The reverse appears to also be true: depression in older adults is associated with significant reductions in active life expectancy (34). Essential is the distinction, sometimes hard to make, between depressed mood that will respond to supportive counseling and more severe depression requiring more aggressive intervention (e.g., psychotherapy, medication, electroconvulsive therapy) (317). Symptoms can include depressed mood, poor motivation, fatigue, and suicidal ideation. The rehabilitation team should maintain a high index of suspicion for the presence of depression that may require aggressive treatment. Vegetative signs suggestive of more severe depression may include the following:

- Sleep disturbance
- Loss of appetite
- Constipation
- Impaired concentration
- Poor memory
- Psychomotor retardation (171).

Other less specific complaints include other somatic symptoms such as pain and ill-characterized dyspnea (169). Depressed patients may appear as if they have a dementia syndrome (312,313).

In many patients with mild reactive depression, the activity and milieu of the rehabilitation unit will alleviate the depression. Progress in therapy and the support of peers and staff often are therapeutic. When the depression is more profound, antidepressants may prove helpful; however, medical contraindications may limit or preclude their use (312). Medications such as trazodone and the selective serotonin reuptake inhibitors (SSRIs) have lower anticholinergic activity and should be considered in addition to those tricyclic antidepressants with the fewest anticholinergic side effects (e.g., doxepin, nortriptyline, desipramine) (313). Doses should be started low, usually at night initially, and increased gradually.

Few studies have investigated the role of psychological and social interventions for older persons (312,314). Depressed outpatient volunteers in generally good health have shown benefits with cognitive behavior, interpersonal, and short-term psychodynamic therapies. Clinically, interventions like

these are potentially beneficial and require more evaluation, especially because medication alone cannot address such associated issues as altered life role (especially with disabilities), chronic medical illness, and losses of a spouse and/or close friends (171,314).

### Anxiety

Anxiety syndromes are another frequent problem during rehabilitation (318). Symptoms can manifest in multiple systems, as in depression. Careful differential diagnosis is required to distinguish between primary anxiety disorders and those secondary to medical illness or medication. A detailed interview and chronology of onset are needed, and assistance from psychiatry often is needed. Diagnostic categories include adjustment disorder with anxious mood, generalized anxiety disorder, posttraumatic stress disorder, and panic attacks (319,320). When feasible, nonpharmacologic interventions, such as behavioral management techniques, physical therapy for muscle relaxation, or psychotherapy, should be used first (321). Nonetheless, judicious and appropriate medication use is frequently necessary to control anxiety symptoms and facilitate participation in the rehabilitation process. Commonly used options include lorazepam, buspirone, imipramine, and SSRIs (320,321).

A baseline anxiety disorder may be exacerbated by hospitalization, leading to agitation with nonpurposeful excessive motor activity. Depression, as well as preexisting psychoses, can also present with agitation (318). The former usually responds to the more sedating tricyclic antidepressants (e.g., doxepin). Paraphrenia is an example of a psychosis occurring in the elderly that often presents with agitation (321). This paranoid psychosis, with onset typically late in life, is characterized by bizarre paranoid delusions in a socially isolated person. Antipsychotics are critical to the management of this problem, coupled with therapeutic alliance with a physician and an attempt to redevelop social contacts for the patient. A history of preexisting psychiatric disorders should always be investigated in the agitated patient. Schizophrenia can continue into old age, although exacerbations respond well to antipsychotics (318).

### Delirium

Delirium, a syndrome characterized by the acute onset of fluctuating cognitive deficits in conjunction with attention disorder and disorganized thought, can cause sleep disturbances, hallucinations, and agitation (322,323). It occurs more often in patients with prior cognitive impairments and can coexist with a dementia, making accurate diagnosis very difficult (324). Any acute medical illness can present in the older person with delirium without the classic signs of the underlying acute illness (199). Infections, dehydration, stroke, hypothermia, uremia, heart or liver failure, and pulmonary emboli are the most common examples of this phenomenon (325). Drug toxicity is another frequent cause of delirium in the elderly, with common offenders including neuroleptics and narcotics (324,325). There are evolving data on factors associated with

postoperative delirium states (326). Delirium is still present in 16% of admissions to postacute facilities, presenting diagnostic and management challenges in the SNF setting (327). Delirium represents a medical emergency, with significant independent morbidity (328); identifying the cause is critical to its resolution (199,323).

### Dementia

Severe dementia occurs in about 5% of individuals over 65 years of age (with mild to moderate forms in another 10%) and in about 20% of those over 80 years of age (329,330). It is found in more than half of nursing home residents and is the most common precipitating cause of admission (329). Women appear to be affected more frequently than men. Insidious onset of memory loss, loss of abstract reasoning and problem-solving ability, impairment of judgment and orientation, and personality changes with relatively intact alertness and awareness are all hallmarks of the disease (331). A patient with early dementia, premorbidly not interfering with daily activities, can become severely disoriented during an acute hospitalization (191,199,332). This agitated confusion may resolve without any specific therapy in 1 to 2 weeks. Appreciation of this possibility is important with regard to evaluating and working with this population in the rehabilitation setting.

Fifty to sixty percent of dementias represent dementia of the Alzheimer type, and another 20% are multi-infarct in origin (330). The remaining large number of potentially reversible causes of dementia include the following conditions:

- Subdural hematoma
- Brain tumor
- Occult (normal pressure) hydrocephalus
- Syphilis
- Hypothyroidism or hyperthyroidism
- Hypercalcemia
- Vitamin B<sub>12</sub> deficiency
- Niacin deficiency
- Drug toxicity
- Depression
- Cardiac, renal, or hepatic failure (331)

Diagnostic evaluation should always be performed to rule out these possible causes. Even if one of these potentially treatable etiologies is established, however, reversibility of the dementia may be limited because of permanent damage from the condition (333). Although there are differing guidelines for recommended laboratory tests for evaluating dementia (331), a standard dementia workup, in addition to detailed history and physical examination with cognitive screening, should include at least a complete blood count (CBC), blood chemistry profiles (including electrolytes, creatinine, BUN), erythrocyte sedimentation rate, and thyroid function studies.

Other investigative studies, such as serologic testing for syphilis, serum folate, serum cobalamin, drug screening, collagen vascular profile, urinalysis for heavy metals, or imaging of the brain (e.g., CT [computed tomography], MRI [magnetic resonance imaging]), can be undertaken if there is concern that

they will clarify the etiology, such as multi-infarct dementia versus Alzheimer's disease (331,334). A trial off all medications, if possible, probably is warranted in all patients with new onset of dementia. Many clinicians also routinely give a trial of antidepressants to newly identified dementia patients because occult depression frequently coexists with mild dementia (198,335). Amelioration of the depression may improve overall functioning in this situation.

Patients with moderate or severe dementia can be limited in their ability to learn in the rehabilitation setting because their ability to form new memory is poor. Day-to-day carry-over may be limited and makes certain types of therapeutic gains difficult to achieve (336). A rehabilitation trial may still be justified in such situations to clarify learning abilities and to train the family in appropriate care of a patient with a new disability. For instance, the patient may show the ability for procedural learning (learning by performing the activity) even if declarative learning (learning from verbal instruction) is impaired (184,207).

When evaluating the elderly patient for admission to a rehabilitation program, it is critical to determine the mental status before onset of the new disability by talking to family or others who have observed the patient. Too often the mental status as seen in the acute hospital setting underestimates the patient's cognitive function when healthier and in a more supportive and stimulating environment (337).

Discharge planning for patients with dementia needs to include family education as to the nature of the patient's cognitive strengths and weaknesses and how to handle potential behavioral problems (184). Community resources for adult day care and respite care programs may be very helpful for families, as well as educational materials like the Alzheimer's Disease Education and Referral Center (ADEAR) website for family and healthcare professional information.

Pharmacological treatment of older patients with severe dementia, particularly with behavioral disturbances, is controversial and confusing. In 1995, the Food and Drug Administration (FDA) issued "black box" warnings for atypical (second generation) antipsychotic medications in elderly patients, due to multiple clinical trials documenting greater mortality risk (339,340). This left clinicians with unclear choices for treatment of elderly dementia patients with psychosis and/or agitation. However, other investigators conclude no increased risk from use of either atypical antipsychotics or conventional neuroleptics (341). Current treatment guidelines emphasize shared decision making with caregivers, thorough documentation, and frequent monitoring (339,340).

## Common Geriatric Syndromes

### Incontinence

An all too common complication, devastating to patient self-esteem and family commitment to patient care, is urinary incontinence. For diagnostic classification and evaluation procedures, the reader is referred to Chapter 51. Several recent reviews cover this topic thoroughly (342–345). Treatment

for incontinence in the older patient hinges on proper diagnosis (See Tables 59-3, 59-4), which usually is possible with a complete history of the problem combined with careful neurologic, pelvic, rectal, and mental status examinations. Laboratory studies should include urinalysis, culture and sensitivity, serum creatinine and BUN, and a postvoid residual urine volume (342,346). A voiding diary often is helpful in determining the nature of the problem, and cystometrics/urodynamics may also be indicated (347).

Treatment is directed at the cause of the incontinence. Unfortunately, many of the etiologies have no uniformly successful therapy, and there may even be multiple causes. A timed voiding program is useful in many patients, offering toileting opportunities at regular intervals to try to maintain continence (342). Initially, the intervals are very short (e.g., every 15 to 20 minutes), with a progressive increase as indicated. Modifications of this technique include patterned urge-response toileting (PURT) (348) and functional incidental training (FIT) (349), with reports of excellent success in nursing home settings.

Surgical procedures may be useful in the treatment of prostatic hypertrophy and sphincteric incompetence (343,347). Anticholinergics (e.g., tolterodine, trospium) frequently are useful in the management of detrusor instability, but with the potential risk of retention (257). Other pharmacologic approaches include direct smooth muscle relaxants (e.g., oxybutynin) and imipramine (342,343). Overflow incontinence due to detrusor decompensation (from overstretching) may require long-term indwelling catheterization, although frequent intermittent catheterization and cholinergic drugs to stimulate detrusor contraction may be helpful (350). Excellent patient and health care professional educational materials are available (351,352).

Bowel incontinence may imply severe bilateral brain disease or loss of sensory input from the rectal ampulla (353). Biofeedback has been shown to be helpful in managing sensory bowel incontinence (354,355), but the management of incontinence secondary to diffuse brain disease usually requires a behavioral approach with bowel movements induced by suppositories at regular intervals (353).

### Sleep Disorders

Sleep disorders and daytime fatigue are related problems common in the hospitalized elderly person as well as those living in the community (200,205,356). The hospital environment alone can disrupt the sleep cycle, an effect further compounded by foreign routines (vital sign checks and medication administration at odd hours), unfamiliar noises (from machines, overhead paging, and neighboring patients), and the depression often associated with the onset of new major chronic illness (205). Sleep deprivation at night leads to fatigue during the day. Napping during the day further disrupts nocturnal sleep patterns, and a vicious cycle can ensue (356).

It is important to document whether insufficient sleep is actually occurring because patients can complain of sleep difficulties when no problem is documented and they

remain alert throughout the day. Simple reassurance in such cases is warranted. In cases of documented sleep disorder, contributing factors such as delirium, medication toxicities, depression, anxiety, restless leg syndrome, chronic pain syndrome, or nighttime medical problems (e.g., congestive heart failure, angina) should be considered (199,205). It is also important to differentiate acute insomnia from chronic insomnia. Acute insomnia (present for <1 month) is often related to a stressor (e.g., bereavement) and is treated with support and short-term, intermittent medication. Chronic insomnia (persisting for >1 month) should be viewed more as a symptom of another illness (356). Hypnotics should be used judiciously and only if other interventions, such as improved sleep hygiene and treatment of the underlying illness, are unsuccessful.

After addressing these issues, good sleep hygiene practices may help. These include a regular sleep schedule, keeping the patient out of the bed and bedroom until bedtime, a snack before bedtime, daily exercise, relaxing activities in the evening before bedtime, and instruction in mental imagery or deep breathing relaxation techniques to be used as needed in bed at night (357). In addition, patients should not watch clocks during the night. Naps during the day should be avoided unless absolutely needed, briefly after lunch.

Only if these interventions fail should a sleep medication be considered. Selected antidepressants can be used in low doses at night to take advantage of sedative side effects, while minimizing anticholinergic activity (e.g., trazodone) (358). If a benzodiazepine-type hypnotic is used, the choice should be one with a very short half-life (e.g., zaleplon, zolpidem) to avoid accumulation with hangover effects (359,360). In general, diphenhydramine should be avoided because of anticholinergic effects (299,300). In the patient who remains persistently fatigued without clear organic cause, occult depression should be suspected (198,311). Additional non-medication treatments that appear promising in older adults include behavioral treatments (e.g., stimulus control to induce good sleep hygiene behaviors) and increased exposure to light (361,362). Recent research indicates melatonin can be a useful adjunct in the management of sleep disorders in the elderly (363,364).

## Pain

Pain is very common in older people, and studies are increasingly focused on this subject (365–367); prevalence estimates range from 25% to 50% of community-dwelling elderly people to 45% to 80% of nursing home residents (366,368). The consequences of pain are significant and include depression, decreased socialization, sleep disturbance, impaired ambulation, and increased health care use and costs (365). The pain experienced and reported by older people is no less threatening than that experienced by younger people and similarly, must be addressed promptly (366).

Special considerations in managing pain in older persons include difficulty in assessment secondary to patient fears, the higher incidence of comorbid illnesses compared with

younger persons, complications in reporting pain in patients with memory and other cognitive impairments, validity difficulties with proxy reporting, and the importance of assessing functional implications of the pain (366,369). Furthermore, physicians understandably tend to attribute new pain to prior conditions (e.g., osteoarthritis). Cognitive impairment does not mask pain at the time of patient questioning, but accurate reporting of past pain is not necessarily reliable (370). Patients may be able to respond appropriately to pain intensity scales concerning current pain, with visual cueing as needed and taking short attention spans into account (371). Special functional considerations include the recognition that advanced and elective ADLs may be more sensitive to changes in pain.

Common etiologies of pain in older people include osteoarthritis, cancer, herpes zoster, temporal arteritis, polymyalgia rheumatica, and atherosclerotic peripheral vascular disease (368). Approaches to pain management are similar across age groups and include use of physical modalities (e.g., heat, cold, massage), transcutaneous electrical nerve stimulation (TENS), biofeedback, hypnosis, and distractive techniques (365). Concurrent depression with pain may occur as in younger persons, requiring direct assessment for depression and intervention if required (313). Of note, older patients with depression are more likely to report pain as a somatic expression of their mood disturbance (370).

Medications for pain should be prescribed judiciously and in conjunction with nonpharmacologic approaches (365). Acetaminophen remains one of the best initial medications to be used routinely in patients with pain (372,373). Nonsteroidal anti-inflammatory medications are problematic in this population, given the limited study of patients over age 65 (374) and the known fourfold higher risk of peptic ulcer disease (375). Long-term use of opiate analgesics is appropriate for malignant pain and probably in some cases of nonmalignant chronic disabling pain unresponsive to other medications. Tricyclic antidepressants or anticonvulsants may be useful in treating neuropathic pain (365). Physical mobility and activities should be encouraged as much as possible. All these treatments are best administered as part of a multidisciplinary team approach, regardless of the setting (e.g., home, SNF, or outpatient department) (366).

A particularly challenging clinical population includes older adults who experience chronic pain, often with repeated failures to respond to traditional medical or surgical treatments. The cognitive-behavioral model of therapy, developed with younger persons, may prove useful in these patients (366,367). This therapy is safer, more effective, and probably lower in cost than a long-term analgesic regimen, especially if applied early in the course of an evolving pain syndrome. This model divides contributory factors to the pain experience into biomedical variables, psychological variables (e.g., pain coping strategies, depression, personality), and socioenvironmental variables (e.g., social support, spousal criticism). Behavior therapy encourages wellness behaviors, and cognitive therapy helps patients reassess how they view themselves and their pain experience. This model also

highlights the importance of assessing family behaviors in the presence of pain. Specific interventions for family coping can be beneficial (376,377). Family and caregiver training, as well as semiformal social supports in the community, may be especially important in the setting of chronic pain in older persons (366). For example, chronic back pain sufferers (typically with associated depression) tend to exhaust their social support (378). Preventing the resulting social isolation would likely improve efficacy of treatment intervention and avoid a cascade of complications (196).

### Falls

Many of the age-related physiologic declines in multiple organ systems combine to increase dramatically the incidence of falls in the elderly, including visuoperceptual difficulty, postural instability, impaired mobility, orthostatic hypotension, lower-extremity weakness, and vertigo due to degenerative or vascular changes in the vestibular apparatus (224,225,379). Other factors contribute to increase the risk of falling, including environmental hazards, adverse effects of medications, concomitant acute or chronic disease states, depression, apathy, or confusion (330,380–382). A model attempting to identify the degree of risk for recurrent falls stratified patients into high and low risk depending on sitting and standing balance, walking ability, and stair climbing (383). In addition, attitudes toward risk were measured, as were social supports and environmental status. Recurrent falls were associated with impaired mobility, risk-taking behavior, and environmental score.

Prevention of these injurious falls is more problematic. A recent prospective study of 9,516 community-residing white women (average follow-up 4.1 years) found that the likelihood of hip fracture increased in the presence of multiple risk factors and low bone density (384). Suggested possible interventions to decrease risk include maintaining body weight, walking for exercise, avoiding long-acting benzodiazepines, minimizing caffeine intake, and treating impaired visual function. Tai chi reduced risk of multiple falls by 48% in a randomized control trial in community-residing persons 70 years of age and older without chronic illness, many of whom had fallen in the prior year (385). Whether this intervention would work for older persons with chronic illnesses needs to be assessed. In another study of community-dwelling elderly with at least one risk factor for falls, a multifactorial intervention (medication adjustments, behavioral instruction, and exercise) reduced falls from 47% in the control group to 35% in the intervention group (386). What multiple studies appear to consistently substantiate is that exercise is an important component of any fall prevention strategy (387–389).

Fear of falling resulting in decreased mobility is also a clinical problem in many older adults (390,391). Patient training in fall recovery techniques and education regarding adaptive and preventive strategies are being evaluated as methods to help prevent activity restriction from the fear of falling (392).

## REHABILITATION INTERVENTIONS FOR COMMON DISABLING CONDITIONS IN OLDER ADULTS

### Hip Fracture

Although 95% of falls in older persons fortunately do not result in serious injury (393), hip fractures continue to be one of the most serious sequela (394). Strategies considered for intervention to prevent hip fracture have included both public health initiatives (e.g., emphasizing weight-bearing exercise) and individualized approaches focused on high-risk patients (395–397). The most effective approaches have yet to be worked out. In situations involving rehabilitation of an elderly patient after repair of hip fracture secondary to fall, it is critical to evaluate, and treat, the cause of the incident fall to prevent future recurrence.

A number of controversies involve proper care of the elderly patient after hip fracture. The literature is increasingly evaluating factors affecting outcomes from hip fractures and potential cost-effective changes in practice (398–402).

Issues relating to preoperative decisions include how long to wait for medical stabilization. One guideline suggests that hip fracture patients who have two or fewer comorbidities should have the operation within 2 days of admission but that a longer delay is beneficial for patients with three or more comorbidities (403). Another study found that a delay of greater than 4 days, or delay due to the management of acute medical problems, resulted in increased mortality (404).

Several factors affect the decision to operate and selection of the most appropriate type of surgery. A tendency to treat hip fractures conservatively (i.e., nonsurgically) in elderly patients with dementia is countered by findings of better function with less morbidity and mortality with surgical management (405). For patients with severe cardiovascular disease that contraindicates general anesthesia, percutaneous pinning with Ender rods under local anesthesia can be performed. Femoral neck fractures can be treated either by resection of the femoral head with endoprosthesis with immediate postoperative weight bearing or by internal fixation with multiple pins with delayed weight bearing. Although intertrochanteric fractures traditionally are managed by internal fixation with nail or compression screw with delayed weight bearing, some studies suggest patients can be mobilized much earlier without complication and with improved morbidity and function (398,401,405).

The postoperative period can be divided into the acute hospital period and posthospital (or postacute) care. The urgency of early mobilization after repair of hip fracture is twofold: the vulnerability to many postoperative complications (e.g., pulmonary problems, thromboembolism, genitourinary sequelae, delirium) and the risk of secondary complications from bed rest or relative inactivity (398,399). In one recent study of the acute hospital period after surgical repair of hip fracture, factors associated with discharge directly to home (which occurred in only 17% of 162 hip fracture survivors) included prior community residential status, age under 85 years, absence

of postoperative complications, achieving independence in bed mobility and ambulation with a walker, and a greater number of physical therapy sessions during hospitalization (401). Also, early initiation of physical therapy has been found to be beneficial for improving mobility in the first 2 months after hip fracture (406).

By far, the majority of hip fracture patients in the United States receive postacute hospital care in other facilities—either acute rehabilitation hospitals/units or skilled nursing facilities. These settings are increasingly necessary as hospital length of stay continues to dramatically decline. Which setting is best for which patient is still not clear, although a recent prospective evaluation found that hip fracture patients had greater functional recovery at 12 weeks with treatment in an acute rehabilitation setting as compared to an SNF (407). What is necessary during the recuperative phase from hip fracture, regardless of setting, is close attention to the multiple medical problems that can arise (399,400). Optimal length of stay in these settings likewise is not yet clear and also continues to decline.

### Arthritis and Joint Replacements

Management of arthritic conditions in older people, just as in a younger population, must be individualized with close monitoring of benefits (405,408). Treatment principles are comparable, although the balance between rest and activity is much more delicate because of the adverse sequelae of inactivity in the elderly. There is evidence that older people with arthritis may respond better to therapeutic programs and often are more patient and compliant with long-term exercise and activity programs (409,410). Treatment goals include relief from fear, fatigue, stiffness, and pain; suppression of the inflammatory process; prevention or correction of deformity; and maximizing function (373,409). This is accomplished via a combination of psychological, pharmacologic, physical, and surgical measures.

Important psychological approaches have been developed through the Arthritis Self-Help Course. The multifaceted interventions include education and exercise (411). Part of the benefit may derive from facilitating the patient's ability to manage his or her own chronic condition. Successful exercise interventions include programs of focused muscle strengthening (e.g., quadriceps strengthening for osteoarthritis of the knee), general conditioning, and aerobic activities (412–414).

Patients can be educated about the beneficial results of using various assistive devices to maintain independent community living, such as a firm chair of appropriate height with armrests, utensils with built-up handles, elevated toilet seat with grab bars, or ambulation aids (e.g., cane, walker). As with any patient care equipment, having patients try to use various devices before purchase will help ensure actual functional use (373).

Pharmacologic interventions for pain control should start with acetaminophen (up to 2 to 4 g/day) (372,373). Opiates (codeine or hydrocodone) can provide additional analgesia for breakthrough pain. Topical capsaicin cream may be helpful for

persistent knee or finger pain, although usage may be limited by cost, need for frequent application, and initial burning sensation with application. NSAIDs may be needed for control of pain and inflammation but with great care and close monitoring given the increased risk of acute renal impairments and GI bleeding (372). In older patients with a history of gastritis or ulcers who require use of NSAIDs, concurrent administration of misoprostol or other cytoprotective agents should be considered (373,415). The use of the nutraceuticals glucosamine and chondroitin sulfate has been controversial in terms of efficacy but is currently the focus of a National Institutes of Health multi-center trial (416).

A limited number of intra-articular steroid injections can be considered (generally no more than two to three per year for any joint) but with anticipation of only short-term benefit (373). The FDA has approved another type of intra-articular injection (hyaluronan, a glycosaminoglycan) for patients who have failed other forms of therapy (373).

Age should not be a primary factor in considering potential benefits of surgical intervention in the elderly arthritic patient (372,416). Significant functional gains may be realized with an appropriately timed procedure (e.g., ligament or tendon repair, osteotomy, arthroplasty, prosthetic joint replacement) to improve stability and range or to decrease pain (409). Attention to preoperative and postoperative therapy programs and early mobilization is critical to maximize functional gains and minimize secondary complications from inactivity. Further details of rehabilitation management, including principles for prescription of medication and therapeutic modalities, can be found in Chapters 31, 40, and 61–66.

### Stroke

Appropriateness of intensive rehabilitation for older stroke patients sometimes is questioned, given the limited and sometimes conflicting research data. Studies to date suggest that age may have a negative or no effect on functional outcomes, that elderly stroke patients may require longer lengths of stay to achieve the same functional gains as younger patients, and that functional outcomes may be similar in differing rehabilitation settings (417–427). The most significant aspects of rehabilitating elderly stroke patients relate to the severity of their neurologic and functional deficits, medical stability and impact of their frequent multiple comorbid conditions on endurance, and their ability to understand, cooperate, and learn in therapy sessions. Severe language or cognitive deficits, significant neglect or apraxia, poor balance or endurance, or recurrent medical complications/instability may negatively impact the feasibility and goals of a rehabilitation program. Clinical practice guidelines for stroke rehabilitation that incorporate these and other variables have been published (428). It is clear that depression, a common complication after stroke at any age, is particularly problematic in older patients due to the deleterious effect on cognitive functioning (429). There is evidence of potential to enhance neural plasticity after stroke, even in older individuals, with improved functional recovery (430). Research continues in an effort to clarify the most appropriate

(and cost-effective) role, timing, methods, setting, intensity, and duration of rehabilitation services for older people after stroke (427,431). Chapter 23 reviews concepts of stroke rehabilitation in detail, with reference to older patients.

### Amputation

Although a detailed review of rehabilitation of patients with dysvascular amputation can be found in Chapters 45 and 74, several aspects require emphasis here. An ageist bias may result in the belief that a patient's age should be a factor in determining whether or not to prescribe a prosthesis. Other comorbidities rather than age *per se* are the relevant determinants for prosthetic fitting (427,432,433). A number of studies have documented the successful outcomes of rehabilitation programs for older amputees, including bilateral amputees and amputees with concurrent hemiplegia (433–437). Even in the face of severe medical comorbidity (e.g., cardiovascular disease), a prosthesis still may be both therapeutic and functional, even if only from the standpoint of standing, transfers, or cosmesis (432). For bilateral amputees, although energy costs are significantly higher and ambulation training more difficult, prosthetic fitting still may be useful to allow periodic standing during the day and for walking short distances in the home, which are therapeutic from both an aerobic exercise and psychological standpoint (434). Wheelchair locomotion will usually be a preferable alternative for longer distance travel in view of significantly lower energy costs and ability to stop and rest. The former criterion of successful crutch ambulation to justify prosthetic prescription is not appropriate (432,433).

### Spinal Cord Injury

Although SCI usually is considered a disability occurring primarily in the younger population, there is increasing recognition of its significance for older people. Not only is there a significant incidence of SCI in a growing older population (5.4% in the 61- to 90-year-old age group) (438), but there is also increased survival rate in an aging population injured earlier in their lives (439). The result is a much higher prevalence of older SCI patients, subject to the usual age-related morbidity and mortality. Similarities have been observed between aging morbidity and that of chronic SCI patients who are not old (440).

Epidemiology of SCI with older age at onset differs from that of younger populations. The etiology of injury is much more likely to be falls (60% in the 75-and-older age group), followed by motor vehicle accidents (32% in the 75-and-older group) (438,441,442). SCI from metastatic disease and cervical myelopathy occurs primarily in older adults. There is a marked increase in proportionate incidence of quadriplegia (QC) and quadriparesis (QI) in the elderly (67% in the 61- to 75-year-old age group, 88% in the 75-and-older group), as opposed to the more nearly equal distribution between paraplegia (PC) and paraparesis (PI) and QC and QI in younger age groups (438). Elderly SCI patients are much more likely to be QI as opposed to QC (441).

There is a progressive disparity in 10-year survival rates between SCI and non-SCI populations with advancing age at injury (438). For those 70 to 98 years of age, the grouped SCI 10-year survival rate is 32%, compared with 48% for their non-SCI counterparts. Life expectancies reported for SCI patients differ depending on whether patients who die before discharge from rehabilitation programs—usually within the first year post injury—are included in the analysis. If such first-year fatalities are included, life expectancy for SCI patients injured at 60 years of age is 6.5 years for PI, 5.9 years for PC, 4.2 years for QI, and 1.9 years for QC, compared with 20.0 years for the non-SCI population (438). Two-year life expectancy is 59% for SCI patients between 61 and 86 years of age, compared to 95% for their younger counterparts (439,443). Older patients with SCI were more likely than their younger counterparts to develop various medical complications, such as pneumonia, GI hemorrhage, pulmonary emboli, or renal stones (444,445). Although overall survival post-SCI is reduced for older adults, with increased morbidity, there does not appear to be a direct relationship between age and functional outcome (446,447).

These significant life expectancies, and potential for functional gains, make rehabilitation efforts appropriate for all patients following SCI, regardless of age (445,446). Rehabilitation goals should be comparable with those for a younger SCI population (see Chapter 27), except as impacted by comorbidity (e.g., arthritis with limitation of hand function, deconditioning, etc.). Personal care assistance becomes more critical with regard to ability to return to the community to live.

### Traumatic Brain Injury

Although the concerns regarding falls in older persons are focused primarily on the risk of hip or other skeletal fractures, there is evidence of a significant incidence of traumatic brain injury as well (448,449). Similarly to older individuals after stroke, the rehabilitation interventions after brain injury must factor in premorbid and current cognitive status, severity of neurological and functional deficits, and comorbidity issues. Experience with the federally designated Traumatic Brain Injury Model Systems Project reveals that elderly brain-injured patients are capable of significant functional improvement, but more often at a slower pace (with longer lengths of stay and higher costs) (448,449). A further consideration in the differential diagnosis of an older individual with new onset of cognitive deficits in the context of multiple falls may be the possibility of a postconcussion syndrome, rather than a traditional etiology of dementia (450). Chapter 24 provides detailed rehabilitation approaches to traumatic brain injury.

## GERIATRIC REHABILITATION PERSPECTIVES

### Geriatric Rehabilitation Settings

Older people with disabling medical conditions may have difficulty tolerating and participating in an intensive inpatient rehabilitation program, owing to such factors as severity of deficits, medical comorbidity, and deconditioning (451,452).

Combined with the quest for least costly health care alternatives, the ideal system of inpatient rehabilitative care would provide for varying levels of intensity and settings (268). Indeed, there is evolving interest in the role and effectiveness of various levels of postacute rehabilitative care, encompassing hospital-based comprehensive or “acute rehabilitation,” SNF, or nursing home-based “subacute rehabilitation,” long-term acute care hospitals (LTACHs), or outpatient clinic-based therapies. Each of these settings offers varying degrees and frequency of physician involvement in medical care and supervision and varying frequency and intensity of rehabilitation therapy treatments. Outcome studies continue to address the question of which older patients, with what underlying disability, will benefit most cost-effectively from which level(s) of care, and at what time postonset of disability (425,426,451,452).

Another nontraditional setting for rehabilitation is the day hospital, which provides comprehensive, relatively intensive and structured rehabilitation therapies designed to reverse disability and train family members to facilitate maintenance of the patient at home (453,454). This provides a greater intensity of therapy, with a wider array of equipment, under closer medical supervision, than usually is feasible in a home-based treatment program. Day hospitals may allow earlier transition from inpatient rehabilitation hospitals/units to the more familiar and comfortable home setting, with lower health care costs (453).

There is also an increasing interest and program development in augmented home care services, including rehabilitative care (455,456). New and innovative programs to provide intensive, rehabilitation services in the home are being developed and tested (457). A randomized controlled trial of an occupational therapy preventive assessment and treatment program for older people living in the community showed improvements across various health, function, and quality of life domains (458). Such community-based programs may prove cost-effective and feasible and help resolve accessibility problems in both urban and rural settings.

These alternative levels and settings of rehabilitation services for older adults provide the potential for a continuum of care, facilitating individually tailored rehabilitative care that can be modified to meet an individual patient’s changing needs over time. Further research is required to document the cost-effectiveness and benefits of these varied rehabilitation programs, particularly among subsets of different disability and age groups.

### Critical Issues Relating to Outcomes

The rehabilitation approach to care of older individuals with disability, like geriatric care in general, must be longitudinal in perspective and coordinated with other aspects of the individual’s health care, not episodic and in isolation. The team work background and training of the physiatrist are an ideal base to accomplish this critical goal of geriatric care.

There are a number of critical issues impacting the quality, cost-effectiveness, and outcomes of rehabilitation interventions. Determining the appropriate treatment setting, timing, and duration of care is of obvious importance. Coupled with

this is the need for individualized, realistic, functional, and relevant goal setting, which includes engagement by the older patient during formulation. Facilitating access to needed services is critical, whether referencing insurance coverage or physical transportation to the care setting. In keeping with the longitudinal perspective, periodic reevaluation is necessary, with review and revision of therapeutic goals as warranted.

Even though “maintenance” treatment or activity is typically unfunded (as opposed to “restorative” care), the concept nonetheless is appropriate. By “maintaining” an older individual’s functional status, he or she can stay in the community at far lower costs than if institutionalized. Waiting for a patient to deteriorate from lack of “maintenance” care risks initiating a cascade of complications with concomitant decreased prospects of regaining premorbid function. It is also important to remember the potential benefits of group therapy/activities (e.g., peer support and encouragement, even friendly competition), as opposed to individual treatment.

The need for patient and family education and training, perhaps on multiple occasions or even continually, should be recognized with respect to compliance and follow-through with health care recommendations and treatment. Finally, the longitudinal perspective mandates long-term follow-up to monitor for complications, recidivism, or underlying disease progression (with prompt intervention, if necessary), as well as to assess counseling or respite needs.

### Role of the Physiatrist in Geriatrics

Physicians from various specialties traditionally have had differing perspectives on their respective roles in geriatrics (459). Psychiatrists may serve a variety of roles relating to geriatrics, depending on the practice setting. These contributions range from providing primary care in a rehabilitation inpatient hospital setting or subacute (SNF-based) setting (336,460) to consulting in various health care settings (e.g., acute care hospital, SNF, day hospital, or home health care) to outpatient care (336,402,453). In the latter settings, the physiatrist assesses functional and medical statuses, works closely with therapy staff, helps formulate appropriate rehabilitation goals, helps coordinate interdisciplinary team care if needed, and monitors the efficacy of therapy.

Hoenig provides an interesting analysis of rehabilitation providers, noting that physicians of whatever specialty typically act at the disease or impairment level (e.g., prescription of medication, surgical procedure, etc.), may function as rehabilitation team leaders, and are often designated as gatekeepers in facilitating access to rehabilitation services (via prescription of therapies, insurance authorization, etc.) (461). She points out that there is a great deal of overlap and variability in the roles played by various rehabilitation providers, with a need to network, communicate, and coordinate to best serve the needs of older patients.

Further progress in this regard is demonstrated by an interdisciplinary interaction and consensus process among ten medical and surgical specialties, spearheaded and funded by the American Geriatrics Society and John A. Hartford Foundation,

respectively (462). As part of this process, Strasser et al. articulate the overlapping principles and complementary treatment approaches of geriatrics and physiatry and the importance of improving the consistency and level of expertise of all physiatrists regarding geriatric rehabilitation, to facilitate improved health care and functional outcomes for our older patients (463).

## Primary Care for Persons with Disability

The issue of providing quality medical care to all persons has been brought to the forefront with the current changes in medicine and health care reform. Terms such as “cost containment,” “appropriate utilization of resources,” and “quality management” are heard by practicing physicians on a daily basis in reference to their patient care interactions. The impetus to make changes in our current health care system has also been influenced by economic issues (1). Health care costs have increased exponentially in recent years, and even though these costs have risen significantly, patients’ health outcome and satisfaction have not risen proportionately. When the United States was compared with numerous other countries with respect to health outcomes and satisfaction in relation to cost, the United States ranked lowest of the nations studied, compared with countries such as The Netherlands, which was among the best (1). When the same countries were compared with respect to their percentage of primary care physicians, the results were similar, with the United States having the smallest percentage of primary care physicians and the countries with greatest satisfaction having the greatest percentage of primary care physicians. When the cost factor is eliminated, however, health care quality in the United States is among the finest in the world. Unfortunately, it is not accessible and available to all. Because of lack of income, lack of insurance, isolation, language, culture, or physical disability, millions still face barriers to quality health care.

The U.S. Department of Health and Human Services’ Health Resources and Services Administration (HRSA) has seven strategic goals that support its mission. They are as follows:

- Improve Access to Health Care
- Improve Health Outcomes
- Improve the Quality of Health Care
- Eliminate Health Disparities
- Improve the Public Health and Health Care Systems
- Enhance the Ability of the Health Care System to Respond to Public Health
- Emergencies
- Achieve Excellence in Management

The 2008 budget for this organization approximates \$5.8 billion, some of which is allotted to those with disabilities. The Bureau of Primary Health Care within the Health Resources Service Administration is allotted \$1.98 billion for 2008 (2).

Although there is general consensus in the United States and abroad that primary care is a critical component of any health care system, there is considerable imbalance between primary and specialty care in the United States (3). The proportion of specialists in the United States is more than 70% of all patient care physicians, whereas in other industrialized countries, 25% to 50% of physicians are specialists (3). There are multiple factors and forces that have led to the dissatisfaction with primary care fields. Medical students are choosing non–primary care specialties at a greater rate each year. The percentage of U.S. medical graduates choosing family medicine decreased from 14% in 2000 to 8% in 2005 (4). Issues such as noncompetitive income, excessive/unpredictable work hours, and concerns about patient outcomes due to shorter and more rushed office visits have also led to 75% of internal medicine residents eventually choosing to be subspecialists or hospitalists, rather than general internists (4).

Further work has shown that based on staffing patterns in classic health maintenance organizations (HMOs), there are about 3.1 times more pathologists, 2.5 times more neurosurgeons, 2.4 times more general surgeons, 2.0 times more cardiologists and neurologists, 1.9 times more gastroenterologists, 1.8 times more ophthalmologists, and 1.5 times more radiologists in the nation than would be needed (3). Although it is clear that there is a plethora of specialists and a need for greater primary care services, considerable room for debate remains on its true impact on health care costs and quality of patient care.

Beginning in the late 1980s and continuing to the present, recognition of the difficulties that persons with disabilities face in accessing quality health care has become apparent. Persons with disabilities represent approximately 10% of the world’s population, yet they are among the most underserved groups (5). Although the medical literature is relatively sparse on this issue, multiple conferences and publications have addressed this topic. The Association of Academic Physiatrists and the American Academy of Physical Medicine and Rehabilitation have both previously developed position statements on the provision of primary care services to persons with disabilities, lending their support to physiatrists who choose to provide these services; however, there are a variety of opinions among practitioners as to how these services are best provided (6,7).

This chapter provides an overview of the primary care issue, with special emphasis on persons with disabilities, as well as a discussion of issues on health promotion in this

population. A practical approach to primary medical care in a general population that can easily be adapted to persons with disabilities follows. The chapter concludes with a review of several models of primary care and describes management issues more specific to those with disabilities.

## DEFINITIONS OF PRIMARY CARE

The HRSA has defined primary care based on the following three anchoring principles: (a) the routine medical care and services people receive on first contact with the health care system for a particular health incident, that is, prevention, maintenance, diagnosis, limited treatment, management of chronic problems, and referral; (b) assumption of longitudinal responsibility for the patient regardless of the presence or absence of disease (i.e., all of a person's health care needs—physical, psychological, and social—are met); and (c) integration of other health resources when necessary (gatekeeper function) (8).

The Institute of Medicine (9) has provided a definition as well, which states that primary care is the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community. “Integration” includes comprehensive, coordinated, and continuous services. “Accessibility” refers to eliminating geographic, financial, and cultural barriers to seeing the caregiver. “Health care services” includes hospitals, nursing homes, office, school, home, and intermediate care facilities. “Clinicians” can be physicians, nurse practitioners, physician assistants, or similar health care practitioners. “Accountable” refers to the clinician being responsible for quality of care, patient satisfaction, efficient use of resources, and ethical behavior. “Majority of personal health care needs” describes the full spectrum of physical, mental, emotional, and social concerns. “Sustained partnership” is a long-term relationship that includes health promotion, disease prevention, and the management of disease itself. “Context of family and community” includes an understanding of the patient's social background and support systems.

Another approach at defining primary care is from the patient's perspective (10). A primary care physician is a trusted physician who (a) performs all preventive care necessary to safeguard health, (b) diagnoses and treats self-limiting conditions, (c) diagnoses serious conditions and either treats those for which he or she has expertise or refers the patient to the best available expert for treatment. A strength of this functional patient-oriented definition is that it delineates the three tiers of health care provided by all primary care physicians.

Primary care may be distinguished from specialty care by the time, focus, and scope of services provided to the patients (3). Primary care as noted above is first-contact care on entry into the health care system. Specialty care generally follows primary care upon referral from the primary care provider. Whereas primary care addresses the person as a whole,

specialty care usually focuses on specific diseases or organ systems. Because primary care providers see patients at their initial interface with the health care system, they are presented with a variety of symptoms and concerns that may represent early stages of disease that are not yet easily classified into specific diseases or organ systems. Through the various roles of the primary care provider, but especially the gatekeeper function, referral to specialty care occurs when organ- or diagnostic-specific disease is identified that is beyond the scope of services provided by the primary care provider. Although primary care is comprehensive in scope and is present throughout the continuum of care, specialty care tends to be limited to specific illness episodes, the organ system involved, or the disease process identified.

## PRIMARY CARE ISSUES IN GRADUATE MEDICAL EDUCATION

Three specialties typically are thought of as primary care fields. The largest is general internal medicine, followed by general pediatrics and family practice. Obstetrics and gynecology, although regarded by the American College of Obstetrics and Gynecology and the American Medical Association as a primary care provider for women, does not traditionally fulfill this role because it does not meet the “whole body” medicine criterion often cited as the standard for judging whether a specialty offers primary care (11). Nevertheless, it is clear that many women consider their gynecologist to be their primary care provider (12).

In its third report (13), the Council on Graduate Medical Education (COGME) stated that generalist physicians are trained, practice, and receive continuing education in a broad set of competencies to care for the entire population in office, hospital, and residential settings; provide comprehensive age- and sex-specific preventive care; evaluate and diagnose common symptoms; treat common acute conditions; provide ongoing care for chronic illnesses and behavior problems; and seek appropriate consultation for other needed specialized services. Given these required competencies, COGME concluded that family physicians, general internists, and general pediatricians are properly trained to function as generalist physicians. Although other physicians provide elements of primary care, COGME also noted that physicians who are broadly educated as generalist physicians provide more comprehensive and cost-effective care than do other specialists and subspecialists (14).

The recent emphasis on health care system reform has sparked the decades-old debate as to who is a generalist physician and has reemerged with important implications for physician workforce policy and medical education (14). In its third report (13), COGME recommended that the nation set a goal that at least 50% of all physicians be practicing generalist physicians. The Association of American Medical Colleges (AAMC) recommended that a majority of graduating medical students be committed to generalist careers (15). Both COGME and

the AAMC define generalist physicians as residents who complete a 3-year training program in family medicine, internal medicine, or pediatrics and who do not subspecialize. Given the enhanced role and growing prestige of the generalist physician and the increased emphasis on primary care, other physician groups, including physical medicine and rehabilitation (PM&R), have suggested that they be included in this category (6,14). In its fourth report (16), COGME stated that the designation of a specialty being included as primary care should be based on an objective analysis of training requirements in disciplines that provide graduates with broad capabilities for primary care practice. In an analysis of the training requirements of numerous specialties, including those typically thought of as primary care specialties (family practice, internal medicine, pediatrics) and several that have proposed inclusion as a primary care specialty (emergency medicine and obstetrics and gynecology), only the previously established primary care fields actually prepared their residents in the broad competencies required for primary care practice (14). Although PM&R was not included in the analysis, based on the current training requirements and a similar analysis, it would not fulfill the necessary training needs.

The ability to provide effective primary care or appropriate treatment for life-threatening illnesses not only depends on adequate training but a continued interest in the area of concern, as well as continued experience based on an appropriate number of cases (10). The growing quality agenda and the move toward mandatory Maintenance of Certification by the American Board of Medical Specialties (and Maintenance of Licensure by the Federation of State Medical Boards) shed additional light on the increasing requirements to maintain expertise in primary care activities. It is not enough to be adequately trained during residency in specific aspects of primary care or the treatment of a serious disease or high-risk procedure because this training quickly becomes outdated in the face of the rapid advances in clinical medicine. The individual choosing to be a primary care provider needs to remain current in the management of any condition that is diagnosed and is needing treatment (10).

In its eighth report (17), COGME evaluated five models that attempted to determine projections for the number of physicians needed for the current century. The differences in the five models lie in the degree to which historic increases in the demand for specialists are assumed to continue in the increasingly competitive managed care setting. COGME hypothesized that market forces will at least balance increasing demand for specialty services resulting from new technology. Consequently, increasing demand for specialists was not as anticipated. The ultimate requirement for generalists and specialists will depend on the configuration of future health care systems. COGME anticipated increased utilization of nurse practitioners and physician assistants, both in specialty care and in primary care. The overall trend, however, was felt to be an increased emphasis on generalists within managed systems of care, thus reducing the demand for specialists.

## GENERALIST VERSUS SPECIALIST

Although it is well accepted that there is an imbalance between primary and specialty care, numerous arguments have been advanced by advocates of both the generalist and specialist perspectives (3,13,18). The generalist perspective points to the research that supports the efficacy of primary care and indicates that generalists have broader medical knowledge and skills; are better trained in psychosocial, preventive, and community aspects of care; and provide less costly care and are more accessible, factors that make them preferable to specialists as primary care providers (18). In addition, the generalists' cross-disciplinary skills provide for more efficient referral patterns when using their gatekeeper function.

Specialists, on the other hand, assert that their training before subspecialization is equivalent to generalists, allowing them to deal with primary care issues (similar to generalists) as well as manage problems within their specialty (that generalists might have to refer elsewhere) (18). Numerous studies support the specialist viewpoint that primary care can be provided in an efficient and cost-effective manner by the same practitioner who provides more sophisticated, specialized, and up-to-date medical services (18).

## MEETING THE POSTREHABILITATION HEALTH CARE NEEDS OF PEOPLE WITH DISABILITIES

The traditional distinctions between primary care and specialty care become much less clear when we consider the ongoing postrehabilitative health care needs of people with disabilities (11). Here, the boundaries between primary and specialty care overlap considerably. It is not clear where one ends and the other begins. The handoff from rehabilitative care in the rehabilitation center to primary care in the community is not straightforward. This is best understood when we consider the nature of the ongoing health care needs of people with disabilities and why many primary care issues have significant rehabilitative or functional content.

It is difficult to generalize about the ongoing health care needs of people with disabilities, in part, because different disabling conditions have widely varying pathophysiologies, comorbidities, and functional consequences. These differences often obscure the fact that people with disabilities experience most of the same health conditions experienced by people without disabilities. However, people with disabilities are at greater risk for certain common health conditions than are those in the general population, often experience these conditions differently, and may require a somewhat different and extended therapeutic regimen that takes into account both their underlying impairment and their functional limitations. However, people with disabilities observe that many health care providers are often unable to look beyond the disabling condition to address the health problem that precipitated the provider-patient encounter in the first place.

## SIX CHARACTERIZATIONS

There are many ways one can characterize the ongoing health care needs of people with disabilities relative to those without disabilities. At the risk of overgeneralization, we note six ways in which the ongoing health care needs of people with disabilities are different from those in the general population. These characterizations are limited mainly to people with the types of conditions commonly seen in inpatient rehabilitation settings (19,20).

First, people with disabilities generally have a thinner margin of health that must be carefully guarded if medical problems are to be averted (21). This observation applies to health conditions that people with disabilities share with the nondisabled population (e.g., upper respiratory infection, pneumonia) as well as conditions more likely to appear among people with disabling conditions (e.g., urinary tract infections, renal failure, pressure sores). It should be emphasized that people with disabilities are not “sick” and that most are generally very healthy. However, their impairments and functional limitations often render them more vulnerable to certain health problems.

Second, people with disabilities often do not have the same opportunities for health maintenance and preventive health as those without disabilities. For example, people with mobility limitations usually have fewer opportunities to participate in aerobic activity needed for good cardiovascular health, and people with paralysis may not be able to detect certain health conditions early because they cannot experience pain in certain body regions (21).

Third, people with disabilities who acquired their impairment early in life may experience onset of chronic health conditions earlier than people in the general population. For example, it is believed that people with long-standing mobility limitations are likely to have an earlier onset of coronary artery disease than the general population. Likewise, people with mobility limitations may experience an earlier onset of adult diabetes because of obesity and may experience an earlier onset of renal disease (e.g., pyelonephritis) because of a neurogenic bladder dysfunction (22).

Fourth, people with disabilities who acquire a new health condition, apart from their original impairment, are likely to experience secondary functional losses. Thus, the functional consequences of a new chronic health condition are usually more significant for a person who already has a disabling impairment. The onset of exertional angina or a rotator cuff injury, for example, may require that the person upgrade from a manual to an electric wheelchair and from a conventional automobile to an adapted van.

Fifth, people with disabilities may require more complicated and prolonged treatment for a given health problem than do people without disabilities. For example, using a plaster cast for a broken leg may be complicated by the individual's vulnerability to a pressure sore when the individual has no sensation in the lower limbs. Likewise, a person with a disability may require a longer recovery period after an acute

episode of illness or injury because of preexisting functional limitations that limit a person's participation in various therapies (e.g., using a treadmill or exercise bicycle after an acute myocardial infarct).

And sixth, people with disabilities may need durable medical equipment and other assistive technologies that require some level of functional assessment. Today, these devices are often prescribed by physicians who have only a rudimentary understanding about the fit between various types of equipment and the needs of the individual consumer. A poor fit between the individual and an assistive device can reduce functional capacity and may induce the individual to abandon the device, the combination of which is wasteful for both the individual and society.

These six characterizations are not exhaustive. A more complete characterization will be important in sorting out the respective roles of traditional primary care disciplines and the various specialty disciplines in managing the health care needs of people with disabilities. The six characterizations point out that traditional distinctions lose their meaning when managing the health care needs of a person with a disabling or chronic health condition.

## IMPACT ON HEALTH CARE UTILIZATION AND EXPENDITURES

These six characterizations are borne out in the above-average rates of health care utilization and expenditures among people with disabilities. The 2005 Medical Expenditure Panel Survey (MEPS) provides a broad overview of the health care utilization and expenditure experience of adults with selected functional limitations. Using variables available in the MEPS, we considered persons as having a disability if they meet any one of the following criteria: (a) use mobility aids or equipment, (b) are limited in major activity (work or housework only), or (c) require help or supervision with at least one activity of daily living (ADL) or instrumental activity of daily living (IADL) (i.e., essential tasks for maintaining one's living environment and residing in the community) (23).

Using this definition of disability, individuals with disabilities comprise 15.9% of the adult population (age 18+). Yet, in 2005, they accounted for 37.0% of all physician visits made by adults, 47.6% of all adult prescriptions (including refills), half of all hospital discharges, 64.4% of all nights spent in the hospital by adults, and 47.7% of all adult-related health care expenditures (Fig. 60-1).

The disproportions reported above are also reflected in estimates of the utilization and expenditure experience of individual adults with disabilities. While only 3.4% of adults with disabilities had no health care expenditures in 2005, 23.6% of individuals without disabilities had no health care expenditures. Of those with at least \$1 expenditure, the median expenditure for people with disabilities was \$5,663, compared to \$1,133 for people without disabilities. These figures represent more than a doubling over a 9-year period. Adults with

**FIGURE 60-1.** Percent of total health care utilization and expenditures by adults with disabilities. United States, 2005. (Computed by NRH Center for Post-acute Studies from the 2005 Medical Expenditure Panel Survey.)

disabilities also typically pay more out of their own pocket (\$780) for health care than the nondisabled expenditure paid from all sources (\$326) (Fig. 60-2). (Median total and out-of-pocket expenditures are calculated only for those who had at least a \$1 total or \$1 out-of-pocket expenditure, respectively. Of note, out-of-pocket expenditures do not include health plan premiums.)

## ACCESS TO PRIMARY CARE

Over 80% of disabled persons have at least one secondary medical condition (24). Many of the secondary health conditions experienced by people with disabilities, however, are entirely preventable through scrupulous health maintenance strategies and timely interventions by knowledgeable practitioners before new health conditions become emergent or even life threatening (23,25,26).

People with disabilities often express frustration about the barriers that limit their access to primary care. These barriers can be grouped into (a) process barriers and (b) structural-environmental barriers (27).

*Process barriers* refer mainly to the communication, attitudinal, and knowledge barriers in the provider-patient relationship (27). Persons with disabilities often describe their providers as not being knowledgeable about the management of secondary health conditions and the impact of these conditions on their functional capacities (21,28–30). They remark that they must make considerable effort to educate their primary care providers about their disability and how it needs to be taken into consideration when new health conditions are addressed (31). In other instances, a provider may have difficulty looking past the disabling impairment to also consider the primary and preventive care needs of a patient with a disability. Nearly two decades of studies have made the same observations. In a 1989 survey of 607 respondents with

**FIGURE 60-2.** Median total and out-of-pocket health care expenditures by adults with disabilities. United States, 2005. (Computed by NRH Center for Post-acute Studies from the 2005 Medical Expenditure Panel Survey.)

disabilities (e.g., spinal cord injury, multiple sclerosis, cerebral palsy, postpolio) in the Washington, DC area—a seemingly dated study, researchers found that many people had difficulty finding a physician who was knowledgeable about their health care needs (32). Respondents who had a previous rehabilitation experience often indicated that they consulted with their original physiatrist when they were not confident about a therapy recommended by their primary care physician. Subsequent smaller scale studies underscore the process and communication barriers cited by individuals with disabilities (27,33–35).

Health plans and health care providers are sometimes said to lack “disability literacy” or “disability competence,” akin to “cultural competence,” when encountering individuals with disabilities (36–40). The lack of “disability literacy” and “competence” occurs despite the fact that health plans and providers have considerable contact with individuals with disabilities owing to the disproportionate use of health care services by individuals with disabilities.

*Structural-environment barriers* include the “physical, social, and economic” environment in which primary care services are rendered (27). They include, but are not limited to, the physical layout of the physician’s office building, the medical equipment, the patient’s financial resources, and the business interests of the provider (41). Inaccessible entrances, a lack of adjustable diagnostic equipment (e.g., radiologic equipment, examining tables), narrow hallways, and inadequate parking are all reported examples that can make the primary care visit a difficult experience (42,43).

Primary care providers may prefer to serve only a very limited number of people with disabilities because people with disabilities often take longer to process in the course of an ordinary office visit and slow down a busy office practice (23,44). Primary care physicians serving patients participating in capitation-based managed care plans have even less incentive to serve high-use populations, such as individuals with disabilities.

The rise of managed care beginning in the mid-1990s and continuing into the present is commonly thought to be adverse to individuals with disabilities. Researchers report that managed care has made access to downstream services such as rehabilitation and assistive technology more difficult than under traditional fee-for-service plans (45). Yet, they also report that individuals participating in managed health care plans had a more regular source of primary care than those in fee-for-service plans but also had somewhat less choice as to who their primary care provider would be (23,46).

The persistence of these process and structural barriers is remarkable given the requirements of the 1990 Americans with Disabilities Act (ADA) and its ensuing regulatory requirements. Some requirements of the ADA may not apply to smaller private practices. Yet, the Act has heightened awareness of society’s obligation to better meet the accessibility needs of individuals with disabilities. Recent ADA-inspired litigation involving inaccessible health care facilities has failed to dramatically increase awareness in this area (47,48).

## MULTIDIMENSIONAL CHARACTER OF THE ISSUES

This brief review illustrates how the boundary issues between primary and specialty care, in the case of people with disabilities, need to be addressed at several different levels. First, there is the issue of the functional and rehabilitative implications inherent in many primary care encounters. Second, there is the issue of knowledge base and whether traditional primary care providers are adequately equipped to address the needs of people with disabilities. Third, there is the issue of whether primary care providers have the facilities to accommodate people with disabilities. And fourth, there is the issue of whether our system of health care financing discourages providers, primary care or otherwise, from addressing the primary health care needs of people with disabilities.

## PHYSICAL MEDICINE AND REHABILITATION AS A PRIMARY CARE SPECIALTY

With these issues in mind, the notion of PM&R as a primary care specialty can now be brought into focus. PM&R is the medical specialty that addresses the needs of severely disabled persons. Primary care physicians often refer these patients after a catastrophic illness. When these patients require comprehensive inpatient rehabilitation, the physiatrist usually serves as their primary caregiver during their relatively short hospital stay but subsequently sends patients back to the referring physician for follow-up general medical care. Follow-up visits at the physiatrist’s office typically concentrate on rehabilitation issues (11).

In contrast, patients with spinal cord and brain injuries often present from referring specialists, that is, neurosurgeons and orthopedic surgeons, with no regular primary care physician. After hospitalization, their follow-up care and health maintenance to prevent rehospitalization become major issues. Physicians in spinal cord and brain injury centers often choose to become the primary care physicians for these patients. Because of the specialized and often complex medical needs of the person with severe disability, primary care physicians in the community often welcome the physiatrist’s involvement and encourage his or her assistance in providing for the primary care needs of their mutual patients (11).

Primary care services are often requested, by those persons with severe disability, to be performed at the rehabilitation facility. In a survey (49) of 144 outpatients with spinal cord injury, it was found that 48% considered their rehabilitation physician as their primary care physician. Fifty-one percent of persons also requested that all of their general medical care be provided by the physicians at the rehabilitation facility. The primary reasons for these requests included maintaining continuity of care with the physician who the patients felt best understood their specialized needs, as well as easier integration with the rehabilitation hospital

for other ancillary health needs (e.g., seating clinic, physical and occupational therapies).

Although it appears that many patients would like their primary care needs met by the physiatrists, there is not a clear consensus of whether this is a practical approach to the issue of providing this care. The problems described in developing PM&R as a primary care specialty were outlined partially earlier in this chapter. Additional considerations include manpower or workforce issues, the preferences professed by current practitioners in the field as well as those in training, and concerns dealing with PM&R residency curricula and the ability to provide adequate training in primary care issues based on our present residency requirements.

As previously noted, it is widely believed that there is a shortage of generalists/primary care physicians. There are several ways to reach the goals previously set forth by COGME (13,17) and the AAMC (15). They include having more medical school graduates enter primary care fields, reducing the number of specialty residency positions, and encouraging current practitioners in subspecialties to broaden the scope of their practice to include a more primary care role (50,51). An additional option is to change the current curriculum of some of our residency programs to include more training in primary care issues.

Even with the proposed paucity of generalist physicians, it was widely held in the 1990s that there would be an oversupply of physicians by the year 2000. In fact, in COGME's fourth report (16) and eighth report (17), it was proposed that the number of federally funded entry-level positions in graduate medical education be restricted to 110% of the number in medical school in 1993 and that 50% of the graduates should be generalist physicians. Since that time, others have made alternative suggestions, including expanding the enrollment of U.S. medical schools to fulfill the shortfall between the supply of graduates of U.S. medical schools and entry-level positions in graduate medical education (52). COGME's 16th report (53) in 2005 set a prediction of a physician shortage, with the demand for physicians being significantly outweighed by the supply by 2020. They recommended that medical schools expand the number of graduates by 3,000 per year by 2015 in order to help the predicted shortfall of 85,000 needed physicians in 2020. It was also noted that this increase will not likely meet the needs of the projected increase in demand alone; however, improvements in productivity and changes in the health care delivery system might help achieve balance.

The AAMC quickly followed COGME with their own statement on the physician workforce needs (54). The AAMC noted that between 1980 and 2005, the nation's population grew by 70 million people (a 31% increase). As baby boomers (those born between 1943–1960) age, the number of Americans over age 65 will grow as well. Baby boomers with a disability and those who become disabled as they age are increasing as well. In general, the elderly/disabled average two to three times as many physician visits, therefore approximately 50% more visits to the doctor in 2020 than 2000. In addition,

since 1980, first-year enrollees in U.S. medical schools per 100,000 population has declined annually. Physician retirees will increase from 9,000 in year 2000 to 23,000 in 2025. Also, it is evident that those recently completing residency are among a new generation that are asking for increased quality of life and fewer work hours. Consequently, America will have fewer and fewer doctor/work hours each year relative to our continually growing population (54). The AAMC called for a 30% increase in U.S. medical school enrollment by 2015. This will result in an additional 5,000 new medical physicians annually. They suggested that this could occur through a combination of enrollment increases in existing medical schools and the establishment of new U.S. medical schools. Even with these proposed increases, the AAMC predicts that there will still be a shortfall. With the current trend of medical students moving into more specialized practices (nonprimary care), as noted previously, and the shortfall of physicians being predicted, the need for an increase in primary care providers will be even greater.

In the late 1990s, a workforce study was performed to determine the current and future manpower needs for the PM&R practitioner (55). The model was based on the assumption that current residency capacity as well as utilization of physiatry skills remains constant at its 1994 to 1995 level. The results were that the demand for physiatrists will continue to exceed supply, on average, through the year 2000. Excess supply has emerged and will continue to emerge in selected geographic areas in the future. In order to maintain a level of demand, it was recommended that the field should emphasize the role of physiatrists in providing efficacious and cost-effective health care. An additional option would be to further broaden the scope of practice to include primary care services. An increasing trend of current graduates of PM&R residencies to enter musculoskeletal outpatient practices has also expanded this demand but not in the area of primary care. There is an ongoing effort to reassess the current and future PM&R workforce needs to help us to address our role in the provision of primary care services.

Unfortunately, there are several issues that will likely dampen the success of this effort. The above workforce projection is based on the premise that managed care will continue to grow at a moderate level. PM&R is not typically designated as a primary care provider in our current HMO and managed care systems. In addition, even if PM&R were designated as a primary care provider for persons with severe disability, it is unlikely that this would have a significant impact on the shortage of generalists. The total percentage of currently practicing physiatrists as compared with the total number of U.S. physicians is less than 1% (11). Based on our current training capacity, it is doubtful that there will ever be the number of physiatrists necessary to provide direct primary care for the large majority of persons with disability (11).

Some of the above assumptions are based on the premise that current practitioners and those in training in PM&R are willing to provide primary care services. A previous survey (51) of 106 PM&R physicians (55 physiatrists and 51 PM&R

residents) showed that only 39% agreed that PM&R should be designated as a primary care specialty. The majority also felt that these services should be restricted to those with severe disability (e.g., spinal cord and brain injuries). Overall, 53% felt that physiatrists are competent in providing general medical care, but only 38% were convinced that the current 4-year PM&R residency sufficiently prepares physiatrists to assume the role of a primary care provider.

Current PM&R training and residency curricula do not place a great focus on several areas that are essential to providing primary care services. These include health promotion and education, as well as preventive services (11). Significant changes would need to occur in our current residency requirements to provide the above training. This would likely require extension of our current 4-year training requirement, as well as substantial adjustments to our current residency experiences. A series of recommendations (56) for changes in the current PM&R residency curriculum were proposed to assist PM&R residency programs in providing for education in the provision of primary care. These include applying general preventive care principles and interventions to those with disabilities, expanding the role of “continuity clinics,” publishing a “study guide” on the topic of primary care for the disabled similar to the study guides currently published by the American Academy of Physical Medicine and Rehabilitation, and providing continuing education on common medical problems seen in the disabled and non-disabled population. Additional consideration was given to developing special or added qualifications in primary care for the disabled or expanding the availability of double board certification (current primary care-oriented combined programs involve internal medicine and pediatrics) to include family practice. Proposals such as these would require significant changes in our current training programs that may ultimately result in a negative impact on the continued growth and attractiveness of our field (11). Changes such as increasing the length of residency training and altering “quality of life issues” for residents and practicing physiatrists (the three “Ls” of primary care: low pay, long hours, low prestige) may be viewed as adverse by prospective PM&R residents (11). In fact, this may ultimately lead to further limitation of the accessibility of care to those persons with severe disabilities. Since the publication of the above recommendations, the issue of primary care within PM&R has become less prominent. A primary care special interest group remains within the American Academy of Physical Medicine and Rehabilitation, but there has been little published within our PM&R literature on this topic. There have been no changes or additions in the Accreditation Council of Graduate Medical Education (ACGME) PM&R residency requirements relating to the primary care issue, and no additional qualifications have been developed by the American Board of Physical Medicine and Rehabilitation (ABPM&R). In the late 1980s, however, the ABPM&R approved the concept of a 5 year combined PM&R and Internal Medicine residency. Though not truly accredited as a combined residency program by

the ACGME, it is recognized as a viable option for being doubled boarded in the two specialties as long as both specialty boards (ABPM&R and Internal Medicine) preapprove the individual’s curriculum. Since its inception on July 1, 1990, only 77 physicians have completed the double boarding program, with only one resident currently in the training and scheduled to complete training in June 2009.

Other potential options to ensure provision of primary care services to those with severe disabilities include collaboration with other medical specialties as well as allied health providers. Several models have been developed that include close working relationships of physiatrists with internal medicine specialists, as well as physician extenders, such as nurse practitioners or physician assistants (30). The nature of this collaboration can be achieved in numerous ways; however, at a minimum, it should include physiatric education of the other primary care providers and team ventures with them to provide primary care for this population (11). A more detailed description of these types of collaborations is provided later in this chapter.

## HEALTH PROMOTION IN PERSONS WITH DISABILITIES

The overall life course health profile of an individual with a disabling condition is the result of interaction among our disability management strategies, general health care practices, biologic and socioenvironmental factors, and lifestyle behaviors. Therefore, when physiatrists address the longitudinal health care needs of those with chronic disabilities, they must view disability-related health management and general health-promoting strategies as equally important components of care. In order to do this, they must enhance their frames of reference and incorporate the concepts of health promotion and secondary condition risk reduction.

### Health Promotion and Related Models

Health promotion has several features that overlap with both primary care and medical rehabilitation. Most notable, all three emphasize education and encouragement of self-responsibility, and all address the potential or actual impact of a given physical or cognitive/emotional condition across several dimensions of health. Finally, all address both health maintenance and disease prevention so as to enhance and protect functional capacity over the life span.

As a general concept, health promotion describes all efforts directed toward helping individuals modify their lifestyles and behavior so as to promote a state of optimal health. Health promotion *per se* is not disease or health problem specific. However, the most important health-promoting behaviors recommended, as reflected by the Leading Health Indicators (LHI) in Healthy People 2010, the national health promotion agenda for the first decade of the new century, are: proper nutrition, weight control, smoking cessation, stress management, physical fitness, elimination

of any drug or alcohol misuse, disease and injury prevention, development of social support, and access to health care for regularly scheduled health surveillance to monitor health status (57).

Early 20th century definitions of optimal health emphasized freedom from disease and issues related to hygiene. However, contemporary definitions of health typically reflect its complex multidimensional nature, incorporating biopsychosocial models related to the interaction of physical, emotional, and environmental spheres (58). Indeed, the Department of Health and Human Services defined optimal health as having a “full range of functional capacity at each life stage, allowing one the ability to enter into satisfying relationships with others, to work, and to play” (59). It posits that the pursuit of optimizing health in a given individual is impacted by the interplay between genetics, environment, lifestyle behaviors, personal health care availability, provider performance, and disease/condition management.

The merging of contemporary definitions of health, including the World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF) (60), psychiatry-oriented models of care, and the disabled individual's own perceptions of well-being, can provide a conceptual framework upon which specific health-promoting and secondary condition risk reduction strategies can be formulated within the context of chronic disability. On many levels, the notion of health promotion for individuals with disabilities is a relatively new and emerging area in research and prevention programming. However, the impetus for closing the gap of disparity for this population of individuals is reflected in the agendas of Healthy People 2010, Healthy People 2020, and the relatively recent Surgeon General's Call to Action to Improve the Health and Wellness of Persons with Disabilities (61). The guiding principle for this Call To Action is as follows: “Good health is necessary for persons with disabilities to secure the freedom to work, learn and engage in their families and communities.” There are four goals that will help accomplish this vision (61):

**GOAL 1:** People nationwide understand that persons with disabilities can lead long, healthy, productive lives.

**GOAL 2:** Health care providers have the knowledge and tools to screen, diagnose, and treat the whole person with a disability with dignity.

**GOAL 3:** Persons with disabilities can promote their own good health by developing and maintaining healthy lifestyles.

**GOAL 4:** Accessible health care and support services promote independence for persons with disabilities.

### Health Protection and Secondary Risk Reduction

Intimately related to health promotion is health protection. Health-protecting behaviors, although overlapping to some degree with health-promoting behaviors, emphasize preventive measures that guard or defend an individual against specific injuries or illnesses. Public health interventions designed to protect health have traditionally been conceptualized as

primary, secondary, and tertiary preventive measures. Primary prevention involves risk reduction and includes those activities undertaken to reduce the circumstances that would result in the subsequent development of a disease process or illness. Attention can be directed to the host (e.g., immunization, counseling on lifestyle behaviors), to the environment (e.g., elimination of physical hazards), or to a specific agent, if one is identified (e.g., contaminated water). Secondary prevention emphasizes the early detection and prompt intervention against asymptomatic disease processes in evolution. Screening efforts characterize this level of prevention. Tertiary prevention attempts to minimize disability from existing disease through medical treatment, education, and rehabilitation. Efforts to prevent the development of secondary conditions known to occur in those with specific disabilities incorporate principles from all three of these traditional models of prevention/health protection (62,63).

Expansion of these public health concepts for application among those with disabilities can provide the conceptual grounding for the development of disability-specific prevention protocols. Specifically, primary prevention for those with an existing disability should include appropriately tailored measures to eliminate risk factors for chronic conditions not necessarily directly related to their primary disability. Interventions may include protocols for health-promoting activities such as smoking cessation, weight control, reduction of substance abuse, increasing physical activity if feasible, and screening for age- and gender-specific carcinoma. Tailoring of these measures includes deliberate attention to the economic, logistic, architectural, and attitudinal obstacles to primary health care often encountered by persons with disabilities. The high prevalence rates of lifestyle risk factors amongst persons with disabilities warrants systematic attention to these areas (Table 60-1).

Secondary prevention measures in those with chronic disability should focus on ongoing anticipatory strategies to minimize the adverse health impact over time of the primary disability, superimposed aging issues, or new injuries. Emphasis is placed on early detection of secondary conditions that, if left unaddressed, can have deleterious effects on organ systems, performance of ADLs, and/or community reintegration over time (58,61). Tertiary prevention measures are then activated when appropriate.

**TABLE 60.1** Prevalence of Risk Factors in Persons with Disabilities and Persons Without Disabilities

	Persons with Disabilities (%)	Persons without Disabilities (%)
Current smoker	30.2	21.7
Physically inactive	25.3	13.4
Obese	20.5	18.6

Source: Behavioral Risk Factor Surveillance System, CDC; 2004.

Tertiary prevention incorporates ongoing interval efforts to maximize and maintain functional capacity over the life course. Education in new skills and equipment is pursued as functional abilities change. Strategies to combat secondary deterioration in the performance of instrumental ADLs are pursued with attention directed to stabilizing or improving access to comprehensive specialized care and stabilizing access to personal care assistance/support services. Additional attention may be given to ongoing vocational rehabilitation and problem solving and the socioeconomic disincentives and obstacles often experienced by disabled individuals seeking a place in the workforce.

### Health Literacy: Building a Knowledge Base

Health literacy is the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions (58). It has been shown that thoughtful advice and counsel (i.e., patient education) about behaviors, lifestyle, and self-care practices that influence overall health can have far greater impact on health and longevity than specific screening tests or procedures (64,65). It is for this reason that emphasis on awareness and education is at the crux of health promotion activities. However, the success of health promotion educational efforts depends on a variety of issues that can be grouped into three categories: (a) issues related to health care professionals themselves, (b) issues related to the patient, and (c) issues related to clinical/environmental circumstances (66). Comments here are limited to the first category. Specifically, addressing the former, rehabilitation professionals may lack self-efficacy regarding their knowledge base and skills necessary for education and motivating individuals in health-promoting behaviors. Additionally, their own personal health enhancement beliefs and practices, their underestimating of patient interest or motivation, or their overestimating of patient knowledge will also influence the nature of clinical encounters and related patterns of education or referral (66,67). Continuing medical education activities, collaboration with primary care providers in the community, small group discussion, and case studies can be useful to physiatrists interested in building their knowledge base over time (68,69).

In order to facilitate effective patient education and behavioral change, the rehabilitation professional must have a clear understanding of available epidemiology assessment and intervention information related to commonly encountered disability-related and general health-related issues. Upon establishing this knowledge base, the physiatrist who so chooses can then routinely pose and answer the following questions during routine medical encounters:

1. What are potential disability-related or general health-related problems of which the patient should be aware?
2. What steps are necessary to clarify if the patient is at risk for specific conditions?
3. Is the problem present?
4. If present, what should be done?

Questions 1 and 2 require knowledge of (a) available epidemiologic data and risk factor information and (b) specialty-specific technical assessment skills. Question 3 requires skills in interpretation of the data secured, and Question 4 requires knowledge in appropriate education and therapeutic intervention options (57,70,71). Several factors other than knowledge predict the likelihood that individuals will adopt health-promoting and health-protecting behaviors. While providing knowledge and education are important parts of effective program design, other factors that affect the health decisions of patients should also be considered. Individual perceptions of risks, perceptions of self-efficacy in adopting recommended behaviors, physical and social environmental factors, and the perceived costs and benefits are four factors that inform personal health decisions. Incorporating the message design guidelines presented below can help more effectively promote behavior changes that result in enhanced health status (72).

To this end, investigators (72) have developed five specific guidelines regarding message design:

1. Messages should contain features that relate appropriate levels of risk.
2. Messages should contain features that bolster consumers' beliefs that they are capable of adopting the recommended behaviors.
3. Messages should contain features that promote efficacy of recommendations.
4. Messages should contain features that encourage consumers to overcome environmental and social impediments.
5. Messages should contain features that promote the benefits and minimize costs.

While "marketable messages" are typically considered the purview of educational materials, the physiatrist can incorporate the specific principles into routine physician-patient encounters.

### The Interdisciplinary Assessment of Health

A systematic health assessment is necessary to establish and document an individual's current health status, lifestyle practices, and psychosocial variables that can influence health. Thereafter, goals can be established and pursued in a manner appropriate to the individual's unique circumstances, resources, and personal desires (70). Particular attention must be directed to the social and environmental aspects of living with a disability that are typically of a magnitude sufficiently significant to greatly influence health-promoting activities (69,73–75).

Health risk appraisal (HRA) instruments are often used in the general population in risk factors assessment, education, and behavioral change programs. However, there are no such guideline-driven instruments for use in the disabled populations. Nonetheless, simple icebreaker-type health status assessments designed for use in the general population can be used to stimulate interest and initiate health promotion discussions between disabled individuals and rehabilitation professionals. Additionally, despite the current lack of valid and reliable HRA instruments for those with disabilities, the adoption of certain

**TABLE 60.2** Percentage of Counseling/Inquiries Made at Last Health Maintenance Examination for Persons with Disabilities

general health risk assessment principles related to smoking, weight control, nutrition, physical activity, cancer screening, mental health, and family history risk factors for disease seems appropriate for those with chronic disabilities (66). While the potential benefits of inquiring and counseling related to lifestyle behaviors are known, studies have indicated that individuals with disabilities are often not asked about these dimensions of health during routine visits. It is posited that medical attention is often directed to disability-specific issues without attention toward general health–screening inquiries (Table 60-2). Table 60-3 provides a partial list of health assessment issues that should be addressed with individuals with physical disabilities. The following section reviews specific general health–promoting activities that should be addressed and encouraged during physiatric encounters wherein the physiatrist is the functional primary provider.

## SPECIFIC GENERAL HEALTH–PROMOTING ACTIVITIES

### Smoking Cessation

Smoking only further compromises a disabled person's already impaired physiologic reserves for good health. Therefore, it is vitally important for physiatrists to encourage and help every patient who smokes, to quit. Cigarette smoking remains the single most preventable cause of death and disability in the United States, accounting for approximately one of every five deaths (438,000 people each year) (76). Approximately 20% of adult Americans smoke cigarettes (77). Over 400,000 Americans die from tobacco use each year—more than the number of individuals who die from acquired immunodeficiency syndrome, cocaine, heroin, gang violence, alcohol, fires, automobile accidents, driving under the influence, suicide, and homicide combined (78–80). Numerous studies have demonstrated

that physicians' advice is a strong motivator and that their efforts to encourage patients to quit do make a difference (78,79,81). Unfortunately, only half of smokers report that their primary care physicians have even asked about their smoking status during the past year (82).

This lack of physician attention to smoking status and smoking cessation recommendations is particularly disturbing in light of the fact that options for office practice–based smoking cessation strategies are readily available from a variety of sources (83,84). The Centers for Disease Control (CDC) and the Agency for Health Care Policy and Research (AHCPR) have produced clinical practice guidelines on smoking cessation (85). Emphasis was placed on assessment and intervention strategies designed to be brief, requiring 3 minutes or less of direct clinician time. Physicians were encouraged to include smoking status (current, former, never) on the vital signs stamp at every clinic/office visit. The practice guidelines recommend that clinicians acknowledge that the majority of smokers who quit smoking will gain weight. Patients should be told that most individuals will gain less than 10lb, although a small minority may gain substantially more (80,86). Follow-up for positive reinforcement or pre-behavioral change encouragement over time is encouraged. The physiatrist and interdisciplinary team, in particular, are often in a relationship with patients wherein cross-discipline reinforcement and follow-through can be instituted during routinely scheduled inpatient or outpatient clinical encounters.

### Nutrition and Weight Control

For many individuals with chronic disability, the promotion and protection of their nutritional health can be compromised by a variety of physical and socioeconomic difficulties. Bulbar signs/swallowing difficulties, limitations in upper-extremity function, income restrictions, and food procurement and preparation difficulties are several confounding variables that can adversely impact food selection and consumption.

Mounting scientific evidence, however, has underscored the direct relationship between diet and health (87). Poor diet has been implicated or identified as a risk factor in several chronic diseases that have become the leading causes of death in the United States: heart disease, diabetes, stroke, and some forms of cancer. In response to this, numerous health agencies, most notably the U.S. Department of Health and Human Services, the American Heart Association, and the National Cancer Institute, developed proposed dietary guidelines for the American population (83,88,89).

For those with disabilities, nutritional health-related secondary conditions can manifest themselves in the form of compromised skin integrity, increased skin vulnerability from cachexia, suboptimal wound-healing capacity, adult-onset glucose intolerance and dyslipidemias (90), bowel evacuation problems, fluid intake–related genitourinary tract difficulties, and functional compromise associated with weight gain. Identifying and reducing environmental, socioeconomic, and disability-related physiologic or functional skills risk factors for poor nutritional health often require a team approach (91).

**TABLE 60.3** Health Promotion Assessment and Health Maintenance Activities in Those with Physical Disabilities: Secondary Impairment and Secondary Disability Screening and Early Detection Activities (*Continued*)

Physical Health Functions	Assessment
Functional status	Anticholinergic use for detrusor hyperreflexia Gallstone disease Colon cancer (age specific) Symptomatic hemorrhoids (bleeding: dysreflexia-inducing) Interval changes in function secondary to changes in strength; endurance, balance, vision, hearing, hypotension, fatigue levels, pain status, cognition, polypharmacy, access to personal care assistance/transportation/health care resources in community, or life stressors Mobility Cognitive intellectual Communication Social attitudinal Depression Knowledge base regarding physical activity/exercise options appropriate for the nature of their disability Family and social support systems Support systems for primary care providers/family
Nutritional assessment	History and physical examination Body weight HDL and LDL cholesterol, fasting serum glucose Swallowing difficulties Functional, economic, or environmental influences on dietary habits/adequacy of nutrient intake Medication effect on appetite/bowels Nutrition intake/diet composition
Tobacco, alcohol, and substance use evaluation	Smoking/second-hand smoke exposure CAGE screening questionnaire/brief MAST screening tool Adult immunizations Dental health Ocular health

Adapted with permission from Lanig IS. *A Practical Guide to Health Promotion After Spinal Cord Injury*. Gaithersburg, MD: Aspen; 1996:55.

Physiologic and body composition differences in many individuals with chronic disability influence the reliability and utility of standard nutritional assessment tools. Basic biochemical and clinical assessment can be pursued based on principles described elsewhere in this text. Data relating to dietary history, social situation history, and functional status components of the nutritional health assessment can be obtained through the interdisciplinary treating team's collaborative efforts. Action plans can be proposed based on the assembled data.

### Physical Fitness

The cycle of disability has been characterized as a vicious cycle wherein physical disability and dysfunction through physical inactivity and deconditioning leads to additional/perpetuated physical disability and dysfunction (92) (Fig. 68.3). Health promotion and related educational efforts for those with disabilities would therefore be incomplete without the provision of a physical fitness component. Exercise regimens adapted to the characteristic limitations or physiologic vulnerabilities created by their specific impairments/disabilities are a must.

Physical fitness encompasses the physiologic attributes of (a) cardiopulmonary fitness, (b) muscular strength, (c) muscular endurance, (d) flexibility, and (e) body composition. Training principles and programs for those with disabilities have steadily been investigated and/or developed over the past 20 years since the 1996 Surgeon General's Report on Physical Activity and Health included an unprecedented section specifically directed to persons with disabilities (93). Benefits of physical activity, including improvements in stamina, muscle strength, promotion of general feelings of well-being, and modulation of joint swelling and pain associated with arthritis, were cited. The importance and positive correlation of social support and the regular physical activity in those with disabilities were noted.

However, for many with disabilities, physical fitness cannot be defined in terms of the traditional conceptions of fitness in the general population. Rather, it must be defined in a broader sense that encompasses not only appropriately modified descriptions of endurance, strength, and flexibility but also (a) conscientious nutritional health practices to

nourish the body, (b) health practices and medical follow-up to minimize the risk of secondary impairments and disabilities, and (c) a balanced commitment to maximizing functional capabilities in both necessary and discretionary activities of daily living (94).

Well-planned, clinically sound physical exercise can improve cardiovascular and/or peripheral muscle endurance, enhance strength and coordination, and improve flexibility in many individuals with chronic disabilities. Therefore, despite a variety of practical challenges often articulated, the interdisciplinary team should systematically evaluate and recommend physical exercise activities for most individuals with chronic disability. In those with neuromuscular disease, there is a common concern that strength and endurance exercises have the potential to create exercise-induced weakness. This concern can be tempered through specific recommendations for nonfatiguing (intensity and duration of) exercise activities and with monitoring of functional capacity after introduction of regular exercise activities (95). For those with arthritis, isometric exercise programs can often maintain strength if pain and inflammation with movement are particularly problematic. However, attention must be directed to maintaining functional range of motion. Overall, strength and endurance programs for individuals with arthritis have been shown to result in better disease outcomes (96). Exercise programs for individuals with the most common forms of multiple sclerosis can be customized to address issues related to fatigue and heat intolerance. Attention should be directed to balancing frequency, duration, and time of day so that the exercise activity does not compromise the individual's ability to perform activities of daily living (97–99). For those with spinal cord injury, the level of injury will influence the cardiovascular response to exercise. Generally speaking, the higher the level of injury, the more likely a significant reduction in cardiopulmonary capacity and fitness, as compared with those of the nondisabled population (100). However, the gains in peripheral muscle strength and endurance often enhance functional capacity and should therefore be encouraged. Recommendations for adaptation of exercise equipment and regimens to accommodate weakness, sensory deficits, or orthopedic limitations created by various disabilities are increasingly more available through a variety of resources.

### Screening for Substance Abuse

The importance of screening for drug and alcohol abuse in the population with disabilities is necessitated by both the impact of these substances on bodily functions and by the behavioral aberrations associated with excessive use (101). A large percentage of individuals admitted to rehabilitation services with neurotrauma were intoxicated at the time of injury and often had preinjury histories of hazardous ethanol consumption patterns (102–104). Additionally, for some individuals with chronic disabilities, maladaptive coping may include intemperate or frankly abusive alcohol consumption. For others, excessive alcohol consumption may be a form of maladaptive self-medication for chronic pain phenomena. Finally, given the

high prevalence of alcoholism found in the community-based general population studies and the morbidity and mortality associated with alcohol abuse and dependency, public health agencies recommend that screening for alcoholism should be a routine part of every medical evaluation (105). One first seeks to help the problem drinker acknowledge the problem, understand its consequences, and recognize the need for treatment. Thereafter, attention shifts to negotiating and carrying out an acceptable, customized treatment plan (106). Most screening instruments have been designed for substance abuse treatment populations. However, the 4-item CAGE (107) and the Alcohol Use Disorders Identification Test (AUDIT) (108) have been extensively tested and utilized in primary care settings. The CAGE questionnaire was designed as an easy, expedient instrument to evaluate a patient's alcohol usage and to determine if further assessment is necessary (107). Although a limitation of this instrument is that it relies on self-report, it appears that those who drink intemperately are more inclined to give accurate responses to CAGE questions when the questions are part of a series of lifestyle questions that include diet, exercise habits, smoking, and safe sex practices (108). The CAGE interview questions are shown in Table 60-4. The World Health Organization AUDIT (108,109) attempts to identify drinkers whose consumption patterns place them at risk for direct or indirect medical problems and alcohol dependency, before frank dependency has developed. The AUDIT and the guidelines for its use can be downloaded from the National Institute of Alcohol Abuse and Alcoholism Web site [www.niaaa.nih.gov](http://www.niaaa.nih.gov).

The diagnosis of alcohol dependence or abuse involves identifying the quantity and duration of consumption, any physiologic manifestations of ethanol addiction, loss of control over drinking, and damage to physical health and social functioning. Routine screening may facilitate early detection of hazardous consumption patterns before frank dependency or abuse

**TABLE 60.4 The CAGE Questions**

The CAGE should be preceded by this question:

Do you drink alcohol? If yes, how much? How Often?

#### CAGE Questions:

1. In the last 3 mo, have you felt you should cut down or stop drinking?  
Yes No
2. In the last 3 mo, has anyone annoyed you or gotten on your nerves by telling you to cut down or stop drinking?  
Yes No
3. In the last 3 mo, have you felt guilty or bad about how much you drink?  
Yes No
4. In the last 3 mo, have you been waking up wanting to have an alcoholic drink (eye-opener)?  
Yes No

Each affirmative response earns one point. One point indicates a possible problem. Two points indicate a probable problem.

develops (110). Hazardous consumption has been defined as four or more standard drinks per day (or >14 per week) in men and three or more in a day (or >7 per week) in nonpregnant women. A standard “drink” is defined as approximately 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of distilled liquor, the equivalent of 0.6 ounces (14 gm) of ethanol.

Once a problem is identified, a multifaceted, personalized, long-term management plan operationalized in collaboration with available community resources and family should be pursued. Transportation issues, architectural and attitudinal barriers within community-based resource facilities, and appropriate social support are specific challenges to systematic management in those individuals with both chronic disability and substance abuse problems.

## PRIMARY MEDICAL CARE IN THE GENERAL POPULATION

Earlier in this chapter, several definitions of primary care were reviewed. The definitions were notable for the broad spectrum of services a primary care physician must address, including disease prevention, health education, and risk reduction. Additionally, this chapter presented differences regarding the ongoing health care needs of people with disabilities relative to those without disabilities. Several of those differences included people with disabilities having an increased vulnerability to certain health problems, an increased risk that a new health problem may impose significant secondary functional losses, and concerns that a given health condition may result in unusually complicated and prolonged treatment make the attention to health prevention and risk-factor modification in people with disabilities of paramount importance. Arguably, primary care for people with disabilities takes on a more critical role than for people without disabilities.

## The United States Preventive Services Task Force

The United States Preventive Services Task Force (USPSTF) was convened by the United States Public Health Service in 1984. The USPSTF consists of 15 experts from the specialties of family medicine, pediatrics, internal medicine, obstetrics and gynecology, preventive medicine, public health, behavioral medicine, and nursing. Its mission is to systematically review the evidence of effectiveness of clinical preventive services and create age-, gender-, and risk-based recommendations about services that should routinely be incorporated into primary medical care (111). The initial efforts culminated in the *Guide to Clinical Preventive Services* in 1989, with a second edition published in 1996. The current *Guide to Clinical Preventive Services, 2007*, is available online at <http://www.ahrq.gov/clinic/pocketgd07>.

In addition to the USPSTF, there are many other major health organizations that propose recommendations. These organizations, which include the American College of Physicians, the American Heart Association, the American Academy of Family Physicians, and the American Cancer

Society (ACS), oftentimes disagree on recommendations as the literature available for review may be inconclusive.

Most primary care organizations focus their recommendations on the following services, which will provide an outline for the following discussion:

- Immunizations
- Screening tests
- Counseling (discussed earlier in the chapter)
- Chemoprevention

## Immunizations

Immunizations are one of the easiest and most effective ways to prevent potentially catastrophic illnesses. Unfortunately, they are often overlooked during patient encounters that are already full of multiple issues, especially in adults. However, it is incumbent upon primary care physicians to address the need for vaccinations, as one component of preventive services. The following is a list of immunizations, and the appropriate dosing schedules, that are recommended by the Center for Disease Control's Advisory Committee on Immunization Practices (ACIP) (112).

## Childhood Vaccines

For childhood immunization schedule, see Figure 60-3.

## Diphtheria, Tetanus, and Pertussis

A child needs five diphtheria, tetanus, and pertussis immunization (DTaP) shots for maximum protection. The first three shots should be given at 2, 4, and 6 months of age. The fourth (booster) shot is given between 15 and 18 months, and a fifth shot (another booster) is given when the child is about to enter school, at 4 to 6 years of age. When DTaP vaccine is given according to this schedule, it protects most children from all

FIGURE 60-3. Childhood immunization schedule.

three diseases. If a child does get one of the diseases in spite of the vaccine, it will probably be milder than it would have been otherwise.

### **Polio**

There are two types of polio vaccines: inactivated (killed) polio vaccine (IPV), which is an injection, and live oral polio vaccine (OPV). The Centers for Disease Control and Prevention recommends only IPV, except in very limited circumstances. Children should get a total of four doses of IPV. The first two shots should be given at 2 and 4 months of age. The third shot should be given between 6 and 18 months, and a fourth shot (booster) is recommended when the child is about to enter school, usually at 4 to 6 years of age.

### **Measles, Mumps, and Rubella**

Most children get measles, mumps and rubella vaccines all together in a single injection called Measles-Mumps-Rubella (MMR). All three of these vaccines work very well and will protect most children for the rest of their life. Children should get two doses of MMR vaccine. The first is given between 12 and 15 months of age. The second may be given at any time, as long as it is at least 28 days after the first. It is usually given at 4 to 6 years of age, before the child enters kindergarten or first grade.

### **HiB**

Haemophilus influenza type B (HiB) vaccine has had a dramatic impact on *Haemophilus influenzae* type B infection. As soon as the first vaccine was introduced in 1985, the disease began to disappear. Several improved vaccines have been licensed since then, and the age for the first shot has been lowered from 24 months to 2 months. There were an estimated 20,000 cases of HiB disease a year in the mid-1980s, but now there are only a few hundred cases a year.

Children should get either three or four doses, depending on which companies' vaccine is used. All children should get the vaccine at 2 and 4 months of age, and a booster dose between 12 and 15 months. Some children should get an additional dose at 6 months. Children who have passed their fifth birthday do not need HiB vaccination.

### **Pneumococcal**

Until very recently, pneumococcal vaccine was recommended mostly for adults over 65 years old and was not licensed at all for children under 2. The lack of licensing for children was because the only type of vaccine that was available (pneumococcal polysaccharide vaccine) did not work very well for young children. Now, a different type of vaccine (pneumococcal conjugate vaccine) has been licensed that is efficacious for children under 2. Thus, it is finally possible to prevent pneumococcal disease in that vulnerable age group.

Children should routinely get four doses of the vaccine, one dose each at 2, 4, 6, and 12 to 15 months of age. Children who begin the series later may not need as many doses. Children over 5 years old will generally not get the pneumococcal conjugate vaccine.

### **Hepatitis B**

Children can be protected from hepatitis B via immunization with three doses of hepatitis B vaccine. Babies can get their first shot between birth and 2 months of age, the second at 1 to 4 months of age, and the third at 6 to 18 months of age. After the third injection, most children will be protected and will not need booster doses.

### **Varicella**

Varicella vaccine is a live-virus vaccine. It has been used in some parts of the world, such as Japan, for over 20 years. It was licensed in the United States in 1995.

Two doses of varicella vaccine are recommended for children. The first dose should be given between 12 and 15 months of age, while the second dose should be given between 4 and 6 years of age. A child who has already had chickenpox disease does not need to get the shot. Occasionally, even children who respond to the vaccine get a very mild case of chickenpox (about 1% to 2%).

### **Influenza**

Influenza vaccinations for very young children have been a recently added recommendation by the CDC. All children between 6 months and 5 years of age should get yearly influenza vaccinations.

### **Rotavirus**

Rotavirus is the most common cause of gastroenteritis in infants and young children worldwide. Nearly every child in the United States is infected with rotavirus by 5 years of age. In 2006, a live, oral vaccine was licensed for use. Three doses are recommended at ages 2, 4, and 6 months of age.

### **Hepatitis A**

Hepatitis A vaccine is an inactivated (killed) vaccine. All children should receive the vaccination. The first of two injections should be given at 12 months with the second one given 6 to 12 months after the first.

### **Adult Vaccinations**

Some adults incorrectly assume that vaccines they received as children will protect them for the rest of their lives. Generally, this is true, except that

- Some adults were never vaccinated as children
- Newer vaccines were not available when some adults were children
- Immunity can begin to fade over time
- As we age, we become more susceptible to serious disease caused by common infections (e.g., flu, pneumococcus) (113)

The following vaccines are recommended for adults.

- Varicella (chicken pox) vaccine
- Hepatitis B vaccine (adults at risk)
- MMR vaccine

- Tetanus, diphtheria, and pertussis
- Influenza vaccine
- Pneumococcal vaccine
- Human papillomavirus (HPV)
- Shingles

### ***Varicella (chicken pox)***

The varicella vaccine is recommended for persons of any age without a reliable history of varicella disease or vaccination or who are seronegative for varicella. It is also recommended for persons who live or work in environments in which transmission of varicella is likely, such as teachers of young children, day care employees, college students, or military personnel. For persons 13 years of age and older, two doses separated by 4 to 8 weeks are the appropriate schedule.

### ***Hepatitis B***

Hepatitis B vaccine is recommended for adults with multiple sexual partners, a recent diagnosis of a sexually transmitted disease, occupational risk of exposure to blood or body fluids, household contacts and sexual partners of those with chronic hepatitis B infection, injection drug users, and all unvaccinated adolescents. The schedule is three doses, with the second dose 1 to 2 months after the first and the third dose 4 to 6 months after the first.

### ***Measles-Mumps-Rubella***

MMR is recommended for adults born after 1956 without written documentation of immunization, health care personnel born after 1956, and adolescents entering college. Women should be asked if they are pregnant before receiving the vaccine. At least one dose should be given. A second dose should be given a month after the first for people entering college or in the health care profession.

### ***Tetanus, Diphtheria, Pertussis***

Since the 1980s, the incidence of pertussis infection in adolescents and adults has been increasing. As a result of this increase, a new booster vaccine (Tdap) has been developed to include pertussis immunization with the previously standard booster shot of tetanus and diphtheria (Td). Adults between the ages of 19 and 64 should receive a Tdap vaccine every 10 years. For adults who will be in close contact with infants and for health care workers who have yet to receive this new Tdap formulation, the vaccine should be given as soon as 2 years after the last Td booster.

### ***Influenza***

Influenza is a viral illness that occurs yearly from November through March. The elderly, infirmed, and many people with disabilities are most susceptible to an influenza infection that could cause serious morbidity and mortality. Therefore, it is recommended that all adults 50 years of age and older; people with chronic medical conditions, including diabetes, asthma, renal insufficiency, and human immunodeficiency virus (HIV); residents of nursing homes and other chronic care facilities;

and health care professionals receive a vaccination yearly in the late fall or winter.

### ***Pneumococcal Vaccine***

Pneumococcus is the most common pathogen responsible for pneumonia in adults of all ages. Those people most at risk for serious infection and death include the elderly, chronically ill, and immunosuppressed. Therefore, it is recommended that all adults 65 years of age and older, and people with chronic medical conditions, splenic dysfunction, asplenia, multiple myeloma or HIV, receive one dose of the pneumococcal vaccine. Those people vaccinated before the age of 65, or who are at high risk of fatal infection, should receive a second vaccination at least 5 years after the first dose.

### ***Human Papillomavirus***

Genital HPV is the most common sexually transmitted disease in the United States. While many infections are relatively asymptomatic, certain strains of HPV can lead to cervical cancer in women. Given this concern over cervical cancer, in March of 2007, the ACIP recommended that females between the ages of 9 and 26 receive the HPV vaccine. The vaccine is given as a series of three doses, with the second dose 2 months after the first and the third dose 6 months after the first.

### ***Varicella-Zoster (Shingles)***

Shingles is a painful skin rash that is caused by the varicella-zoster virus, the same virus that causes chickenpox. Shingles most commonly develops in the elderly and people who have compromised immune systems from disease or immunosuppressive medications. The ACIP recently recommended that people over the age of 60 receive one injection of the zoster vaccine.

## **Screening Tests**

The three leading causes of death in the United States, in order, are coronary artery disease, cancer, and stroke (114). Concerning coronary artery disease and stroke, the risk of developing these illnesses can be reduced greatly by the treatment of major risk factors. The major modifiable risk factors are hypertension, diabetes mellitus, hyperlipidemia, obesity, and smoking. Regarding cancer, early detection usually leads to improved survival. As a result, screening recommendations exist for the most common cancers in men and women, which include prostate, colon, breast, and cervical cancers.

## **Screening for Cardiovascular Risk**

### ***Hypertension***

In addition to being a major risk factor for coronary artery disease and cerebrovascular disease, hypertension is also a major risk factor for congestive heart failure, renal disease, abdominal aortic aneurysm rupture, and retinopathy. Multiple studies over the last 30 years have demonstrated that reduction in elevated blood pressure leads to a reduction in risk of these diseases regardless of ethnicity, gender, or age (115). The current

screening recommendations from all major authorities call for routine blood pressure measurements at least once every 1 to 2 years in adults beginning between the ages of 18 to 21 (116). In 2003, *The Seventh Report of the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure* (JNC VII) redefined high blood pressure categories to include a prehypertension stage of 130 to 139 systolic or 85 to 89 diastolic (117). This change was made to emphasize that blood pressure readings in the prehypertension category should not be considered normal. People with prehypertensive blood pressure readings should be counseled to lower their blood pressure through lifestyle modification, which includes weight loss, exercise, reducing sodium intake, increasing intake of fruits and vegetables, and limiting alcohol intake.

Lifestyle modification is not only recommended for the prehypertensive category but is considered the initial intervention for all elevated blood pressure readings. If lifestyle changes are not effective at lowering the blood pressure to the desired range, then medications should be started. There are many medications available for the treatment of hypertension. The JNC VII suggests that in uncomplicated stage I hypertension (systolic 140 to 159 or diastolic 90 to 99) a diuretic is most often the first medicine to use. In stage II hypertension (systolic greater than or equal to 160 or diastolic greater than or equal to 100), a combination medicine that combines a diuretic with another agent is recommended as initial therapy. However, in the setting of specific clinical conditions, other choices for initial or subsequent therapy could be considered. Examples of these situations include the use of angiotensin-converting enzyme or angiotensin-receptor blockade medicines in patients with diabetes and congestive heart failure and the use of  $\beta$ -blockers in patients with systolic heart failure or who have suffered a myocardial infarction. A comprehensive list of such indications and medication choices is listed in the JNC VI (118).

### **Diabetes Mellitus**

Diabetes mellitus is an established risk factor for both macrovascular (coronary artery disease, cerebrovascular disease) and microvascular diseases (retinopathy, neuropathy, nephropathy). Careful control of the blood sugar has been proven to reduce the development of these diseases (119,120). Despite this information regarding reduced risk of disease in the diabetic population, most major authorities, including the American College of Physicians, the American Academy of Family Physicians, and the American Diabetes Association, recommend against routine screening for diabetes among asymptomatic adults. The USPSTF finds insufficient evidence to recommend for or against routine screening. However, most authorities agree that selective screening in high-risk individuals is warranted. High-risk people would include those with obesity, hyperlipidemia, a strong family history of diabetes, or women with a history of gestational diabetes.

According to the American Diabetes Association, the best screening test for detecting diabetes is the fasting plasma glucose (FPG). A person with an FPG greater than 125 has

diabetes. A person with an FPG between 100 and 125 has impaired glucose tolerance or prediabetes and is considered to be at an increased risk of developing diabetes in the future. Normoglycemia is defined as an FPG less than 100 (121).

Treatment options for diabetes, both insulin dependent and noninsulin dependent, have expanded significantly over the last several years. Oral agents are available that sensitize cells to the effects of insulin, as well as stimulate insulin secretion. Additionally, the array of insulin preparations available have increased to include longer acting agents that provide a more stable basal level, as well as agents that act quickly to provide better postprandial effects. Although a comprehensive review of these medications is beyond the scope of this chapter, the goal of treatment is to achieve a hemoglobin A1C less than 7.0% (see Chapter 65 for further discussion of the above medications).

### **Hyperlipidemia**

There is a significant body of literature that demonstrates lowering cholesterol levels results in a reduction in primary cardiovascular events (122–124). As a result, most major authorities agree that people should be screened routinely for lipid abnormalities at least every 5 years. Additionally, these same authorities agree that appropriate screening entails obtaining a nonfasting total cholesterol and high-density lipoprotein (HDL) levels. However, there is disagreement as to the age to begin the screening process. The USPSTF and the American College of Physicians recommend screening men age 35 years and older and for women age 45 years and older. For people with other risk factors for coronary artery disease, these organizations recommend beginning the screening process as early as 20 years of age.

The National Cholesterol Education Panel-Adult Treatment Panel III (NCEP-ATP III) recommends that screening begin for all people at the age of 20 by obtaining a fasting lipid profile. The fasting lipid profile should include total cholesterol, low-density lipoprotein (LDL), and HDL levels. Subsequently, a person's cardiovascular risk-factor profile should be determined to help determine their target LDL level. The NCEP-ATP III guidelines were released in 2001, with updated recommendations in 2004. Based on the updated recommendations, people with known coronary artery, peripheral vascular, or cerebrovascular diseases, as well as people with diabetes, should have their LDL value less than 70. In people with two or more cardiovascular risk factors (including hypertension, cigarette smoking, obesity, family history of premature coronary artery disease, and HDL cholesterol less than 40, a man older than 45 years of age or a woman older than 55 years of age), the LDL cholesterol level should be less than 130. However, a person with two or more risk factors that are in poor control should have the level less than 100. For people with less than two risk factors, the LDL cholesterol level should be less than 160 (125).

The initial approach to a person with elevated cholesterol is dietary modification. A diet low in fat and cholesterol should be tried for several months in attempts to

reach the target LDL level. If this level is not reached, then pharmacologic therapy should be instituted. The most common class of medications to treat elevated LDL cholesterol is the statin class. It is important to monitor the effects of these drugs on the cholesterol levels 2 to 3 months after initiating therapy or when increasing the dose. At the same time, careful monitoring of liver function tests is recommended as the statin medications have a small risk of causing elevated liver transaminases.

### **Obesity**

During the past 20 years, there has been a dramatic increase in the rate of obesity in the United States. In 1987, there was no state with an obesity rate greater than 15%. However, as of 2006, there were 46 states with obesity rates greater than 20%, of which 22 states were above 25% and two states were above 30% (126). Furthermore, an estimated 66% of the adult population of the United States is either overweight or obese (127). Persons who are overweight or obese are more likely to have adult-onset diabetes, hypertension, and risk factors for other diseases (128). Observational studies have established a clear association linking overweight and obesity with hypercholesterolemia and suggest an independent relationship with coronary artery disease (129). Obesity has been associated with an increased risk of certain cancers (including those of the colon, rectum, prostate, gallbladder, biliary tract, breast, cervix, endometrium, and ovary) and with disorders such as cholelithiasis, obstructive sleep apnea, venous thromboembolism, and osteoarthritis (130). Finally, obesity can affect the quality of life by limiting mobility, physical endurance, and other functional measures, as well as through social, academic, and job discrimination. Arguably, obese people with disabilities may suffer even greater loss of mobility and endurance than obese people without disabilities.

As a result of the above information linking obesity to a myriad of diseases, the USPSTF recommends that all people be screened for obesity. The most often used modality is the body mass index (BMI). The BMI is calculated through height and weight measurements. A normal BMI is between 18.5 and 25. Overweight is defined as a BMI between 25 and 29.9. Obesity is defined as a BMI greater or equal to 30.

## **Cancer Screening**

### **Breast Cancer**

Breast cancer is the most common malignancy in women in the United States. A woman's lifetime risk of developing breast cancer is approximately one in eight (131). The incidence of breast cancer has actually declined since 2002 presumably due to the decreased use of hormone replacement therapy (HRT) in postmenopausal women (132). From a peak of 203,500 new cases of breast cancer in women in 2002, there were only 178,480 new cases in 2007. Unfortunately, in 2007 there were still 40,460 deaths due to breast cancer. Treatment for breast cancer, especially when detected early, is effective at decreasing mortality. As a result, the ACS, American College of Radiology, American

Medical Association, American College of Obstetricians and Gynecologists (ACOG), and a number of other organizations recommend screening mammography every 1 to 2 years and annual clinical breast examination beginning at the age of 40 and annual mammography and clinical breast examination beginning at age 50 (133).

### **Cervical Cancer**

Approximately 11,150 new cases of cervical cancer will be diagnosed in the United States in 2007, with 3,670 deaths (134). The disease is usually preceded by an asymptomatic phase that is preinvasive and therefore ideal for early detection and treatment. Cervical cancer is caused by human papillomavirus, a sexually transmitted disease in 95% of the cases (135).

A consensus recommendation that all women who are sexually active, or who have reached the age of 18, should have annual Pap smears has been adopted by the ACS, National Cancer Institute, ACOG, American Medical Association, and the American Academy of Family Physicians. The recommendation permits Pap testing less frequently after three or more annual smears have been normal (136).

### **Colorectal Cancer**

Colorectal cancer is the second leading cause of cancer mortality in the United States, with an estimated 52,180 deaths in 2007 (137). Over 90% of colorectal cancer begins as an adenomatous polyp that can often be detected through screening procedures. The ACS, the American College of Physicians, and the USPSTF agree that colon cancer screening should begin at age 50 for men and women at average risk. The ACS recommends screening with fecal occult blood testing plus sigmoidoscopy every 5 years or a colonoscopy every 10 years (138). Increasingly, physicians are recommending colonoscopy over sigmoidoscopy. For patients with a family history of colon cancer, screening should begin either 10 years before the family member was diagnosed with colon cancer or age 50, whichever age comes first.

### **Prostate Cancer**

Prostate cancer is the most common cancer in men and accounts for the second highest number of cancer deaths in men (139). Public awareness of this disease and the opportunity to be screened with a blood test (prostate specific antigen or PSA) have grown tremendously in the last few decades. Unfortunately, there has been no research to date demonstrating that systematic early screening for prostate cancer with PSA or digital rectal examination would save lives. As a result, the USPSTF concludes that there is insufficient evidence to recommend for or against screening for prostate cancer at this time (140). However, the ACS and American Urological Association do recommend annual digital rectal exam (DRE) beginning at age 40, with an annual serum PSA beginning at age 50. PSA screening should begin at age 45 for those men at high risk for prostate cancer, including African American men and those with a family history of prostate cancer (141).

## Chemoprevention

### Aspirin Therapy

Coronary artery disease is associated with well-established risk factors, such as hypertension and smoking. In addition to the commonly discussed risk factors, coronary artery disease has also been related to platelet activity and inflammation. The fact that aspirin possesses both antiplatelet and anti-inflammatory properties has made it an interesting topic regarding coronary artery disease prevention.

There have been five major randomized trials of aspirin therapy for the primary prevention of coronary events (142–146). Four out of the five studies showed a reduction in the rates of cardiovascular events, most notably myocardial infarction. The reduction in relative risks ranged from 4% to 44%.

The USPSTF recently strongly recommends that clinicians discuss aspirin chemoprevention with adults who are at increased risk for coronary artery disease. Increased risk is considered for men older than 40, postmenopausal women, and younger people with risk factors for atherosclerotic disease. Other authorities recommend calculating the risk of coronary artery disease over 5 or 10 years and utilizing aspirin in people who reach a certain threshold of risk.

Unknown in the recommendations is the appropriate dose of aspirin to recommend. The five primary prevention studies used aspirin doses ranging from 75 to 500 mg, and there have been no studies comparing different doses of aspirin.

### Postmenopausal Hormone Replacement

HRT for postmenopausal women has been a controversial topic for the last 20 years. In the 1980s and early 1990s, observational studies suggested that women who were treated with HRT had a lower risk of developing coronary heart disease, had more favorable lipid profiles, and had a better quality of life. Unfortunately, as with all observational studies, there were significant confounding factors. Some of these factors included the fact that women treated with HRT were usually healthier at baseline, more physically active, and were of higher socioeconomic status (147). Further complicating the controversy over HRT was the fact that there was an increased risk of breast cancer in women receiving HRT. The relative risk of developing breast cancer in women receiving HRT was 1.3 compared to the risk in those women who did not receive HRT (determined from meta-analysis). The Women's Health Initiative is a long-term, national health study looking at the effects of HRT, dietary modification, and calcium and vitamin D supplementation in 161,108 women between the ages of 50 and 79. The HRT arm of the trial enrolled women to receive one of three treatments: estrogen and progesterone if they had a uterus, estrogen alone if they did not have a uterus, or placebo. The study was due to be completed in 2005, but due to emerging, concerning trends, the estrogen plus progesterone and estrogen arms were stopped early in July 2002 and March 2004, respectively.

The major findings from the trial were that estrogen plus progesterone increased the risk of heart disease, breast cancer, strokes, and pulmonary emboli. There was a decreased

risk of colorectal cancer and hip fractures. Overall, health risks exceeded benefits of this combination therapy in postmenopausal women (148). Concerning estrogen alone, there were increased risks of strokes and deep venous thromboses, decreased risk of hip fractures, and no clear effect on heart disease or breast cancer (149). Similar to the combination therapy, the health risks exceeded the health benefits.

### Osteoporosis

Osteoporosis is characterized by low bone mass, leading to bone fragility and an increased susceptibility to fractures (150). One out of two women and one out of eight men older than the age of 50 will have an osteoporosis-related bone fracture in their lifetime. The estimated direct expenditure for osteoporosis and its related fractures is \$14 billion annually (150). Specifically concerning hip fractures, there is 15% to 20% risk of dying within 1 year of suffering the fracture (151). Risk factors for osteoporosis include age, Caucasian and Asian women, small, thin body habitus, family history of osteoporosis, cigarette smoking, excessive alcohol intake, medications such as steroids and anticonvulsants, and extended bed rest or inactivity.

The diagnosis of osteoporosis is made by a bone mineral density (BMD) study. Dual energy x-ray absorptiometry (DEXA) is the BMD examination that is most reliable. Osteoporosis is defined as a BMD more than 2.5 standard deviations below the average BMD of young women, while osteopenia is defined as a BMD between 1 and 2.5 standard deviations below the BMD of young women (151).

Many people with disabilities suffer from a loss of mobility and weight-bearing activity. As a result, osteoporosis can develop at an earlier age than average. Obtaining DEXA scans and discussing prevention and treatment of osteoporosis in people with disabilities should be of primary importance.

There are several ways to help maintain a healthy BMD and prevent osteoporosis. First, it is important that people take adequate amounts of calcium and vitamin D. For most people, 1,000 to 1,200 mg of calcium a day and 400 to 800 IU of vitamin D are recommended (152). Furthermore, counseling regarding smoking cessation and moderation of alcohol consumption is important. When possible, weight-bearing exercise should be encouraged.

Medications are available to treat osteoporosis. The most common class of medications used is bisphosphonates. Bisphosphonates work by inhibiting osteoclast-mediated bone resorption. Recently, there has been concern that these medications may cause osteonecrosis of the jaw. However, a recent review of all available studies contends that the risk remains extremely low (153).

### Low Back Injuries

A leading cause of missed days in the workplace, acute low back pain has not yet received the scientific inquiry and educational priority that it deserves. A report from the North Carolina Back Pain Project revealed that treatment from family physicians, orthopedists, and chiropractors had equal success in resolving uncomplicated acute low back pain (154). However,

ambulatory patients surveyed in the study were significantly more satisfied with the care they received from chiropractors, as they reported more satisfaction with the chiropractic clinician's examination and patient education efforts. This study's conclusions should not be surprising because undergraduate and resident medical education programs do not always adequately stress the musculoskeletal examination and even more importantly, patient education and prevention techniques. The AHCPR published clinical guidelines for the evaluation and management of acute low back pain (155). Authorities propose that prevention programs emphasizing weight reduction, proper lifting techniques, ergonomic design of the home and workplace, and strengthening and flexibility enhancement will reduce the incidence of this common condition. However, a more recent update by the USPSTF found no new good evidence for or against the use of back-strengthening exercises or risk factor modification (e.g., increased physical activity, smoking cessation, or reduced alcohol consumption) for the primary prevention of low back pain in adults. There was limited evidence that educational sessions in occupational settings (e.g., back schools) produce modest short-term benefits in adults with recurrent or chronic low back pain, but no evidence that such education prevents back pain in healthy individuals or those at risk for back pain (156).

### Overuse Injuries

Sports-related and work-related overuse injuries present principally in ambulatory medical settings. Therefore, primary medical care providers should be familiar with their evaluation and management.

#### Sports

Exercise is an important risk reducer for the chronic diseases mentioned above. Providers should know how to manage the adverse reactions (overuse injuries) of an exercise prescription, just as they should know how to manage the adverse reactions of medication. Common running and walking overuse injuries include metatarsal and tibial stress fractures, metatarsalgia, Morton neuroma, shin splints, patellofemoral pain syndrome, infrapatellar tendinitis, Achilles tendinitis, pes anserine bursitis, and iliotibial band friction syndrome. Although overuse injuries of the lower limbs are usually precipitated by improper training techniques and excessive exercise duration or intensity, sports medicine practitioners now know that the root cause is often a biomechanical imbalance such as overpronation and inflexibility (157). Thus, a working knowledge of strength and flexibility assessment, biomechanical foot disorders, and proper athletic shoe prescription is an essential requirement of the modern primary care provider.

#### Repetitive Injuries in the Workplace

Because primary care providers aim to view patients in the full context of their home and work, occupational medicine issues are an integral component of comprehensive health care. For example, our "keyboard society" has hastened a dramatic increase in the reporting of carpal tunnel syndrome

cases. Primary care providers must become well versed in the assessment, conservative treatment, and knowledgeable referral of patients with carpal tunnel syndrome and other work-related repetitive injuries.

### Trauma-Related Injuries

#### Motor Vehicle Injuries

In 2006, motor vehicle crash (MVC)-related injuries and other unintentional injuries (MVC was number one among this group) were the fifth leading cause of death in the United States (158). In 2006, the cost of unintentional injuries totaled \$652.1 billion, with motor vehicle injuries being responsible for almost half of this cost (158). Motor vehicle fatality rates are highest for young and elderly adults, whereas injury rates peak in young adulthood (158,159). Although alcohol-related traffic fatality rates have declined by more than one third since 1979 (159), alcohol use remains an important risk factor for motor vehicle injuries. In drivers 15 to 20 years of age involved in fatal crashes between 1992 and 2002, the incidence of intoxication dropped by 7%. Still, 27% of the young male drivers (11% of females) involved in fatal crashes had been drinking at the time of the crash. Evidence also indicates that impairment with drugs other than alcohol also may play an important role in traffic injuries and deaths, although the relationship is not as well-defined as for alcohol. In addition to driving while impaired by alcohol or drugs, failing to use occupant protection (e.g., safety belts, child safety seats, motorcycle helmets) is also an important risk factor for motor vehicle injury (159,160). Substance abuse screening and intervention are likely to be efficacious in reducing motor vehicle injuries and fatalities, whereas the use of occupant restraints has been proven to reduce the risk of motor vehicle injury and death (161).

Recommendations (161) from the USPSTF for the prevention of motor vehicle-related injuries are listed as follows:

1. Clinicians should regularly urge their patients to use lap and shoulder belts for themselves and their passengers while riding in automobiles, including automobiles equipped with air bags.
2. Operators of vehicles carrying infants and toddlers should be urged to install and regularly use federally approved child safety seats in accordance with the manufacturer's instructions and the child's size.
3. Those who operate or ride on motorcycles should be counseled to wear approved safety helmets.
4. All patients should be counseled regarding the dangers of operating a motor vehicle while under the influence of alcohol or other drugs, as well as the risks of riding in a vehicle operated by someone who is under the influence of these substances.

#### Household and Recreational Injuries

Unintentional injuries accounted for nearly 120,000 deaths in the United States in 2006, more than half of these being related to household, recreational, and other etiologies

unrelated to motor vehicles (158). Falls, poisoning, choking/aspiration, fires and burns, drowning, mechanical suffocation, and firearms caused nearly 50% of these deaths (158). Almost 90% of deaths relating to sports and recreation occur during swimming, boating, bicycling, riding off-road vehicles such as all-terrain vehicles, or using firearms (158). All of the above are also common causes of nonfatal injuries, with falls being the most common (161).

Recommendations (161) from the USPSTF for the prevention of household and recreation related injuries are listed as follows:

1. Parents should be counseled on measures to reduce the risk of unintentional injuries to their children from residential fires and hot tap water, drowning, poisoning, bicycling, firearms, and falls.
2. Homeowners should install smoke detectors and carbon monoxide detectors in appropriate locations and test the devices periodically to ensure proper operations. Encourage the use of flame-resistant nightwear during sleep and reduce or cease smoking in the home.
3. Households are advised to keep a 1-ounce bottle of ipecac, display the telephone number of the local poison control center, and place all medications, toxic substances, and matches in child-resistant containers.
4. Bicyclists and parents of children who ride bicycles should be counseled about the importance of wearing approved safety helmets and avoiding riding bicycles in motor vehicle traffic.
5. Families should be encouraged to install fences with gates around swimming pools.
6. All windows that pose high risk for falls should have window guards.
7. All residents of homes with swimming pools, young children, or elderly persons should be encouraged to learn cardiopulmonary resuscitation and maneuvers to manage choking incidents.
8. All firearms should be removed from the home or at a minimum kept unloaded in a locked compartment separated from the ammunition.
9. Elderly patients should be counseled on measures to reduce the risk of falling, including exercise (particularly training to improve balance), safety-related skills and behaviors, and environmental hazard reduction, along with monitoring and adjusting medications.

### Organization of the Medical Care Team

Managed care has dramatically and irrevocably changed the delivery of health care in the United States. Managed care organizations now carefully define the roles of their primary care providers and specialty providers. Powerful practice management computer databases are being developed that track patient populations, case mix and levels of service acuity, resource utilization, prescribing patterns, referral patterns, individual practice profiles, and treatment outcomes. Individual practices, regional health care systems, and Fortune

500 health care conglomerates are implementing continuous quality improvement programs.

A concept in managed care delivery that depends on continuous quality improvement for its success is called disease state management (162). This health care organization model targets high-cost and high-volume diagnoses and those conditions that tend to have wide variations in provider practices and resource utilization. The intention of disease-state management is to improve outcomes while maintaining or lowering overall costs. The process of disease-state management must include evidence-based clinical policies, an accurate and complete database that can measure the well-defined outcomes, and a team-oriented, multidisciplinary approach. The multidisciplinary approach will require careful and extensive communication between generalist and specialist members of the team (163). Advocates of this organizational system recognize that its success critically depends on a sophisticated information system and the rapid development of evidence-based clinical policies that focus on patient outcomes. Unfortunately, outcome studies in primary care need further development. Thus, outcome-based studies will be important research objectives for primary care scholarship.

### Family and Community Issues

Primary care providers assess and treat patients within the context of their family and community. Indeed, comprehensive longitudinal care is incomplete and ineffective without addressing the meshwork of stresses and supports that surround individual patients (162,164). Quality primary care addresses and explores the following family/community issues:

- The family circle
- Patient birth order
- Family genogram
- Childhood traumas, expressed and suppressed
- Family violence
- Marital history and marital stresses
- Chronic illness in other family members
- Family organization and identity (chaotic? crisis-oriented? nurturing? etc.)
- Educational level of the patient
- Educational resources available for the patient and family
- Child day care services
- Health belief models expressed by the patient and family members
- Timing of illnesses in a patient's life-cycle stage
- Patient's work/employment history
- Co-worker stress/support
- Patient hobbies and stress relievers
- Patient's pets
- Home safety
- Neighborhood safety
- Family and nonfamily members living in the same household
- Transportation availability
- Services and support for persons with disabilities

- Financial resources
- Legal difficulties and legal aid services
- Spiritual support (and stress)
- Recreation resources
- Available community health and counseling agencies
- Self-help and support groups
- Respite care for families of the elderly
- Elderly day care programs
- Extended care facilities
- Rehabilitative services
- Hospice

### Model Programs for Provision of Primary Care to Persons with Disabilities

The need to provide primary care services to persons with disabilities is obvious, yet the process by which care can be provided remains unclear. Given that barriers to care exist, some models of care may be more beneficial to persons with disabilities seeking primary care services. Pediatric programs that provide primary and rehabilitation care to children with disabilities are well established; however, innovative models of care for adults are not currently available in most communities.

### Barriers to Primary Care Services

Persons with disabilities experience many barriers to receiving primary care services. Physical barriers to care include problems with transportation and inaccessible parking lots, offices, and exam rooms (23,30,165). Those with physical disabilities have also described difficulty transferring to examination tables, as well as inaccessible equipment for routine tests such as mammograms or pelvic exams (166). Attitudinal barriers to care have been described, as persons with disabilities have reported instances of providers refusing to provide medical care due to unfounded disability concerns or have felt that primary care physicians lack adequate knowledge of their specific disabilities (165,167).

In many cases, physicians themselves impose barriers to care. Many physiatrists, while comfortable treating rehabilitation problems, are not comfortable providing primary care services (51). Beyond the intern year, most PM&R residency programs do not include primary care or basic internal medicine topics in their curriculum. Similarly, general practitioners, who are trained to provide preventive care and to treat acute medical problems, are not adequately trained in how to provide care to persons with disabilities (11,168). Low reimbursement rates for longer office visits amplify a negative stigma, which is often unfairly attached to persons with disabilities (23). Thus, primary care providers who would otherwise be willing to treat persons with disabilities are often hindered by both their lack of training and the cost of providing care. The following will describe four models of primary care for persons with disabilities.

### General Practitioner Model

In a traditional primary care setting, a family medicine physician, internist, or subspecialist physician assumes responsibility

for all primary care issues. In cities where no innovative models for care exist, many persons with disabilities have no choice but to receive primary care from traditional general practitioners, while at the same time receiving separate rehabilitation services from physiatrists. In cases of acquired disability, physiatrists often attempt to refer patients to primary care providers familiar with treating persons with disabilities; however, it may be difficult to find general practitioners who are willing to assume care (11). Studies have suggested that persons with disabilities receive fewer preventive health screens compared to nondisabled peers, suggesting that general practitioners may focus on disability-specific problems rather than routine screening or health maintenance (11,23,166,167). Thus, even though persons with disabilities may have a primary care provider, there still may be unmet needs. Under arrangements where separate medical and rehabilitation services are provided in parallel, there may not be adequate communication between providers.

In contrast to a disconnected system of separate primary care and rehabilitation services, a general practitioner model of care specifically focuses on primary care services for adults with disabilities. In this model, the general practitioner assumes responsibility for all primary care issues related to patient care, using other disciplines and psychiatry services in consultation. A consulting physiatrist manages all rehabilitation issues, but the general practitioner provides all preventive care, treatment for outpatient acute medical problems, and acute care inpatient hospitalization.

One example of a successful general practitioner model is the Anixter Center in Chicago, a nonprofit agency, which is associated with Schwab Rehabilitation Hospital (169). Adults with physical and developmental disabilities are followed in an internal medicine outpatient clinic. The comprehensive service plan includes medical, psychiatric, and psychological services. An internist provides primary medical care, and other specialists, including physiatrists, are used as consultants when needed. Approximately 40 persons with disabilities are seen each day for primary care visits. Patients may be referred for additional services such as training in independent living, substance abuse treatment, and vocational services. Costs are fee for service and Medicaid or Medicare funded.

### Physiatric Model

In the physiatric model, the rehabilitation physician assumes the role of primary care provider. This model of care is most commonly used in cases of spinal cord injury or traumatic brain injury, particularly in younger patients who did not have a primary care physician at the time of injury (11). Under the physiatrist model of care, the physiatrist treats all chronic problems and acute medical issues, in addition to any rehabilitation-specific conditions. Due to lack of support staff and difficulty making expedited appointments, patients may utilize emergency room services for urgent medical problems. All routine screening and health maintenance care become the responsibility of the physiatrist, thus potentially leading to unmet needs as many rehabilitation providers do not have

the time, knowledge, staff, or resources to provide necessary preventive services (11,51).

An example of a successful program where physiatrists provide quality comprehensive care is within the Department of Veterans Affairs (VA) Hospital System (170). Persons with spinal cord injuries receive acute, chronic, and preventive care services from physicians trained in spinal cord injury. Comprehensive care is provided to persons with spinal cord injury in one of 23 regional centers. The spinal cord injury specialist runs a multidisciplinary team that coordinates annual comprehensive evaluations. All inpatient hospital admissions are directed to the spinal cord injury service regardless of the medical problem. Even after undergoing surgery, patients are transferred to the spinal cord injury floor for medical care. Preventive health care, education, emergency services, subspecialty care, and long-term care are all provided through the VA. Additionally, all necessary equipment, vocational programming, social services, and psychological services are offered throughout the veteran's lifetime.

### Collaborative Practice Model

Collaborative practices allow persons with disabilities the opportunity to receive all necessary medical care from multiple medical personnel in a single office setting. Access to primary care, gynecology, urology, and rehabilitation services is made available within the same practice. Medical information is typically communicated in one chart, and patients rarely require referrals outside of the practice. In some programs, patients may receive treatment for all acute problems including urgent and emergency care and inpatient hospital services. Additionally, routine preventive services are provided and chronic conditions are monitored.

The initial concept for a collaborative practice model was developed at the Rehabilitation Institute of Michigan, where persons with disabilities on Medicaid could receive comprehensive care (30,171). The basic team consisted of an internist, physiatrist, and nurse. Specialty physicians such as urologists and surgeons were consulted when needed, and all visits were provided on-site. Urgent care services were provided in clinic, and an answering service was available for off-hours. Any urgent needs were coordinated with the emergency room by the interdisciplinary team. Unfortunately, the program was forced to close when Michigan Medicaid shifted from a fee for service plan to a capitated managed care organization.

Rancho Los Amigos Rehabilitation Center in California is another example of a collaborative practice model, providing primary care to persons who have had spinal cord injuries or strokes (172). At present, a complex system of outpatient clinics provides primary care services, rehabilitation services, annual exams, and subspecialty follow-up at the rehabilitation center. A physiatrist transitions patients from inpatient rehabilitation to any pertinent outpatient clinics. On initial follow-up after discharge from inpatient services, patients are evaluated by therapists in the outpatient clinic as part of care plan development. An internist or nurse practitioner staffs specialized primary care clinics. Clinics for wound management,

pulmonary care, gynecology, orthopedics, urologic care, and spasticity are available in the same building, and all medical records are kept in a single outpatient chart to facilitate information sharing. Although primary care services are predominately used for persons with spinal cord injury, if needed, those with stroke or traumatic brain injury may also receive specialized primary care.

Currently, the Rehabilitation Institute of Chicago (RIC) offers a comprehensive program for primary and rehabilitative care (173). Primary care clinics are available 4 days a week and are staffed by two internists. Patients discharged from RIC with primary care needs may be followed up in the clinic for all primary care services and preventive care. A women's gynecology clinic is also available. One of the major goals of the program is to prevent secondary health conditions and functional decline. Services from therapists, physicians, and allied health professionals combine to provide comprehensive health care, and the same chart is used for all clinic and therapy notes.

### Coordinated Care Model

Previously, separate health care coordination and home-care models of primary care have been described. At its inception, the health care coordination model emphasized the use of nurse health coordinators who performed initial health assessments; developed patient-centered plans of care, coordinated with the primary care physicians and specialists; and provided 24-hour urgent care assistance. The nurse health coordinator facilitated all communication between providers and helped to integrate all services. Similarly, the home-care model described comprehensive patient care based out of the participant's home.

More recently, the health care coordination and home-care models have essentially been combined into a model of coordinated care (174). Disability coordination care organizations have been described as a combination of a home-based model and community nursing services for people with long-term health care needs. A common theme to all coordinated care programs is that of patient autonomy and patient-directed care. Most programs permit medical care to be provided in an outpatient clinical setting or in a participant's home. A nurse or social worker serves as a case manager to coordinate all needed medical and social services. In many instances, case managers will make patient appointments, arrange for transportation to visits, and attend appointments if needed. At the time of enrollment, each participant receives an extensive medical and social evaluation. Although care focuses on treatment and prevention of medical problems, an emphasis is also placed on provision of any services that might enhance quality of life and functional independence.

Most coordinated care models operate under a capitated prepaid managed care system with state Medicaid agencies (175). Some programs also enroll Medicare patients. The goal of disability coordination care organizations is to reduce costs while providing better clinical outcomes. With increased preventive services, the number of inpatient admissions and emergency room visits diminish (174). Start-up costs for coordinated care programs are often high because participants

may have significant unmet need at the time of enrollment. However, after services have been established and medical problems stabilize, costs tend to be contained (174). Some programs receive additional grant support from outside sponsors such as the Robert Wood Johnson Foundation.

The first program of this type originated from the Urban Medical Group in Boston, which provided primary care to inner-city nursing home residents and frail homebound elderly persons (30,174–176). In the 1980s, the Boston Center for Independent Living and the Urban Medical Group created Boston's Community Medical Group with the intent to provide primary care services to persons with spinal cord injury or advanced HIV disease. Currently, Boston's Community Medical Group provides primary care to persons with disabilities as part of the Commonwealth Care Alliance, and approximately 450 patients are enrolled. At the core of the program are nurse practitioners and physician assistants, who serve as gatekeepers to care after initial evaluations are completed. An individualized, comprehensive medical plan is provided to participants in their homes, clinics, long-term care facilities, or hospitals. The physician extenders promptly evaluate new medical problems and provide 24-hour emergency assistance. Interdisciplinary meetings with the physician extender, primary care physician, social worker, therapists, and behavioral health specialist lead to coordination of services. The initial program started as a Medicaid fee-for-service program but later converted to a capitated prepaid managed care organization in conjunction with Massachusetts Medicaid. Participants may be dually enrolled in Medicare.

The Wisconsin Partnership Program encompasses separate organizations throughout Wisconsin under a Medicare and Medicaid capitated program (174,177). Some of the Partnership organizations provide interdisciplinary care to persons with disabilities less than 65 years of age. Most enrollees are at a Medicaid nursing home level of care. A nurse practitioner coordinates care with the primary care provider, nurse, social worker, and other team members. Medical care, long-term care, and community-based services are provided in participants' homes or in the setting of their choice. Emergency care, transportation, and personal care services are also covered. Emphasis is placed on preventive services and patient education. Patient autonomy is an important component of care, and patients are encouraged to choose participating physicians and to direct personal care services. A plan is in place to expand programs so that all sites will be able to provide services to persons with physical disabilities and to those with developmental disorders. As of January 2008, almost 2,700 participants were enrolled in the Partnership program.

The AXIS Health care program in Minnesota is a non-traditional Medicaid managed care program (174,178). It was created in 1997 through a grant from the Center for Health Care Strategies, to help find an innovative way to provide quality, cost-effective care to persons with disabilities. Similar to other coordinated care models, nurses serve as case managers and perform complex assessments on all patients as they enter the program. Nurses are on call 24 hours a day for assistance

with medical issues, and all patient information is available in a portable medical record. Participants are referred to their primary care physicians and specialists as needed, and nurse practitioners are available for episodic care. All program providers have experience in treating persons with disabilities. Care can be received at home, in nursing facilities, or in outpatient clinics. The program provides participants with all needed health care and support services, including physical and occupational therapy, mental health, and substance abuse treatment. Presently 1,100 persons with disabilities are enrolled.

## CONCLUSION

All of us, including persons with disabilities, want the same things for ourselves and our families: a compassionate, knowledgeable, and available physician to help us maintain our health when we are well and to manage our minor illnesses when we are sick, and the best specialists available when we have a major acute or chronic medical problem (11). In this chapter, we have reviewed some of the obstacles that those with disabilities endure to achieve the above ideal. It is not expected that the field of PM&R will be declared a primary care specialty nor would this be a viable solution to providing primary care services for all of those with disabilities. However, one of the goals of writing this chapter was to provide those physiatrists who currently perform continuity of care and gatekeeper functions with some guidelines, as well as resources, to continue to provide state-of-the-art primary care. The majority of practicing physiatrists, however, do not fulfill this role.

Our health care system is changing rapidly, and in order to assist our patients with disabilities to achieve optimal health, we need to frequently reevaluate and modify our methods of health care delivery. The last section of this chapter provided alternatives and models for the provision of primary care services in this population. Some of the programs have become very successful within their own health care systems but may not directly apply to all practitioners interested in providing these services. At a minimum, rehabilitation care providers should collaborate with existing primary care providers, including generalist physicians and physician extenders, to achieve the goal of providing adequate, high-quality primary care for persons with disabilities. This collaboration could include educating primary care providers on psychiatric issues as well as team ventures with them to provide primary care for this population.

PART

VI

# Management Methods

# Therapeutic Exercise

The term *therapeutic* relates to the treatment of disease or physical disorder, and *exercise* refers to bodily exertion for the sake of training or improvement of health. This chapter on therapeutic exercise therefore addresses the use of activities requiring physical exertion in the prevention, treatment, and rehabilitation of illness and disabling conditions. The pertinent exercises considered in this chapter include those to develop endurance, strength, flexibility, and proprioception.

The use of therapeutic exercise in the treatment of injuries is not a new concept. Hippocrates (460 to 370 B.C.) reportedly advocated exercise as an important factor in the healing of injured ligaments, and the Hindus and Chinese used therapeutic exercise in the treatment of athletic injuries as early as 1,000 B.C. Today, the various types of exercise probably account for the most commonly used treatments in the field of physical medicine and rehabilitation. Therefore, it is important for clinicians in the field to have a thorough understanding of this area.

The concepts forming the basis for therapeutic exercise come from studies in basic physiologic science and applied exercise physiology. In recent years, epidemiologic investigations have provided additional insight into the importance of exercise in prevention of disease. Consequently, much of this chapter is devoted to this basic information that provides the foundation for the clinical use of exercise.

## METABOLIC FUNDAMENTALS

Part of adaptation to regular exercise is the development of the energy systems most involved in the type of training being used. Therefore, to condition an individual optimally for participation in a particular activity or sport, an exercise program should be designed to increase the physiologic capacity of the energy systems most important to that activity. For this reason, it is valuable to have an understanding of how energy is derived for muscular contraction.

The immediate usable form of chemical energy for all muscular contraction is adenosine triphosphate (ATP). ATP is supplied to the muscle through three systems: (a) the adenosine triphosphate–creatine phosphate (ATP-CP) system, (b) the anaerobic glycolysis system, and (c) the aerobic system. The relative utilization of the three systems depends on the intensity and duration of the exercise (Table 61-1) (1).

## Anaerobic Metabolism

Anaerobic metabolism refers to a series of chemical reactions that do not require the presence of oxygen. Two of the systems that supply energy for muscular contraction are anaerobic.

### The ATP-CP System

ATP and CP are high-energy phosphagen compounds stored within the muscle and ready for immediate use. The breakdown of ATP produces adenosine diphosphate (ADP), inorganic phosphate, and energy used in muscular contraction. CP is broken down to create energy that is used to reform ATP.

This system provides an immediate source of energy for the muscle and has a large power capacity. In other words, a large amount of energy per unit time can be supplied through this system. However, because of the small stores of ATP and CP, the total capacity for work with the ATP-CP system is limited. In fact, the energy resources from the ATP-CP system will be exhausted in 30 seconds or less during an all-out bout of exercise (2,3).

## Anaerobic Glycolysis System

Glycolysis refers to a series of reactions resulting in the breakdown of carbohydrate into pyruvate or lactate. Anaerobic glycolysis means that this breakdown of carbohydrate is performed in the absence of oxygen.

During maximal exercise that lasts 1 to 2 minutes, lactic acid produced by the skeletal muscles accumulates in the muscles and blood. This is accompanied by an increase in the proton release causing acidosis. Interestingly, lactate acts as a solid indicator of the changes in the acid-base balance but is not the cause of the acidosis. In fact, lactate acts as a buffer for the acidosis that would otherwise have a more rapid onset and produce fatigue even more quickly (4). At any extent, when the concentration of lactic acid is high enough, nerve endings are stimulated, resulting in the sensation of pain. In addition, the lactic acid within the muscle cell inhibits the production of more ATP (5) and the binding of calcium to troponin (6), which is part of the series of events leading to muscle contraction. Therefore, the amount of energy obtained from the anaerobic glycolysis system is limited by these effects. Nevertheless, the anaerobic glycolysis system is extremely important because it can provide a rapid supply of energy.

**TABLE 61.1** Characteristics of the Three Metabolic Systems

Metabolic System	Substrate (Fuel)	Oxygen Required	Speed of ATP Mobilization	Total ATP Production Capacity
Anaerobic metabolism				
ATP—CP system	Stored phosphagens	No	Very fast	Very limited
Glycolysis	Glycogen/glucose	No	Fast	Limited
Aerobic metabolism	Glycogen/glucose, fats	Yes	Slow	Virtually unlimited

Adapted from Fox EL, Mathews DK. *The Physiological Basis of Physical Education and Athletics*. Philadelphia, PA: WB Saunders; 1981.

### Aerobic Metabolism

In the presence of oxygen, glycolysis produces pyruvate, which is further metabolized through the tricarboxylic acid (TCA) cycle (also known as the *Krebs* or *citric acid cycle*) and electron transport system to yield carbon dioxide, water, and energy. Relative to anaerobic glycolysis, the energy produced from a given amount of carbohydrate is about 13 times greater through aerobic metabolism. Furthermore, there are no fatiguing or painful byproducts through aerobic metabolism, and not only carbohydrate but fats and proteins may be metabolized aerobically. Although the ability to metabolize fat means that this system provides a virtually unlimited source of energy, aerobic metabolism provides energy at the slowest rate of the three energy systems.

### The Energy Continuum

All three energy systems supply a portion of energy to the body at all times. However, one energy system may predominate during a particular activity. Which energy systems are predominant during a given activity depends on the rate of energy (power) requirement during the activity (Fig. 61-1)

**FIGURE 61-1.** Relative importance of the different metabolic systems as a function of exercise intensity. (Adapted from Sahlin K. Metabolic changes limiting muscle performance. In: Saltin B, ed. *Biochemistry of Exercise VI*. Champaign, IL: Human Kinetics; 1986;323–343.)

(7). In activities performed at maximal intensity for only a few seconds, most of the ATP is supplied by the ATP-CP system. Activities of lower intensity, such as those at a maximal effort that can be sustained for 1 to 2 minutes, primarily rely on the anaerobic glycolysis system. Longer-duration, lower-intensity activities that may last several minutes or hours are supplied almost entirely through aerobic metabolism.

During a graded exercise test, blood lactate concentration remains relatively constant until a critical exercise intensity is reached, at which time lactate begins to accumulate in the blood (Fig. 61-2) (8). This accumulation does not indicate the onset of anaerobic glycolysis; rather, it is the result of the rate of lactate production exceeding its rate of removal.

### Fuel Utilization

The three fuels that may be used to generate ATP for muscular contraction are carbohydrate, fat, and protein. These fuels differ in the amount of oxygen required for metabolization to the end products of carbon dioxide and water (Table 61-2). Thus, the amount of carbon dioxide produced relative to the amount of oxygen used (the respiratory quotient [RQ]) differs among fuels. During exercise, this ratio is referred to as the *respiratory exchange ratio* (RER) rather than the RQ. This distinction is made because the rate of carbon dioxide exhalation increases out of proportion to metabolism whenever metabolic acidosis exists, as occurs at high exercise intensities. Metabolic acidosis is buffered in the blood by the bicarbonate buffering system with nonmetabolic carbon dioxide produced as a byproduct and in the muscle cell by the phosphate system. Therefore, at maximal exertion during dynamic exercise, an RER greater than 1.1 is expected. In fact, an RER greater than 1.1 is frequently used as a criterion to assess whether maximal exertion was achieved with graded dynamic exercise testing.

Because fat serves as the primary form of stored energy in the body, it is fortunate that it has a caloric density that is much higher than carbohydrate (9.3 kcal/g, compared with 4.1 kcal/g). However, slightly less energy (4.7 kcal/L, compared with 5.0 kcal/L) is produced from every liter of oxygen when fat is used than when carbohydrate is used. Amino acids can also be metabolized to produce energy for muscular actions, although this contribution is generally 10% or less.

The fuel used during exercise is influenced by several factors, including the exercise intensity and duration, pre-exercise

**FIGURE 61-2.** Schematic demonstration of the determination of maximal oxygen uptake. **Left:** Oxygen uptake increases during 5-minute exercise stages on a bicycle ergometer at different workloads (noted within the *shadowed area*). **Right:** Oxygen uptake at each workload measured after 5 minutes, plotted in relation to workload. Note that there was no additional increase in oxygen uptake between the 250- and the 300-W workloads. Maximal oxygen uptake is 3.5 L/min. Blood lactic acid concentrations across each workload are also demonstrated. (With permission from Astrand PO, Rodahl K. *Textbook of Work Physiology: Physiological Basis of Exercise*. 3rd ed. New York: McGraw-Hill; 1986.)

diet, mode of exercise, and level of fitness. As the intensity of the exercise is increased, the predominant fuel source shifts toward carbohydrate. This is partly because ATP production shifts toward anaerobic metabolism during high-intensity exercise and carbohydrate is the only fuel available for anaerobic glycolysis. Carbohydrates are made available to the contracting muscle through mobilization of muscle and liver glycogen stores as well as through ingested carbohydrates that are circulating in the bloodstream.

Exercise duration also has an effect on the fuel utilization pattern. Fat usage gradually increases during long bouts of exercise. Free fatty acids are made available to the contracting muscle through lipolysis of triglycerides within extramuscular (e.g., adipose) and muscular stores. The type of diet consumed before exercise affects fuel utilization during exercise. During prolonged exercise, carbohydrate is more likely to be used when one has been eating a diet rich in carbohydrates (Fig. 61-3) (9).

**TABLE 61.2** Characteristics of the Different Metabolic Substrates

Fuel	Energy Content (kcal/g)	Oxygen Equivalent (kcal/L)	Respirator Quotient (RQ)
Carbohydrate	4.1	5.0	1.00
Fat	9.3	4.7	0.70
Protein	4.3	4.4	0.80

The mode of exercise can also influence the fuel source used during exercise. Exercise that localizes the work to a small muscle mass will tend to use a greater proportion of carbohydrate as fuel.

Finally, training status can affect the composition of the fuel used during exercise. Adaptations to endurance training increase the ability of muscles to use free fatty acids as a fuel while sparing glycogen (10,11).

**FIGURE 61-3.** Effect of three different diets on fuel source used during running. Vertical bars represent the points at which exhaustion occurred. (Based on data from Christensen EH, Hansen O. *Arbeitsfähigkeit und Ernährung*. *Skand Arch Physiol*. 1939;8:160–175.)

## Oxygen Uptake

*Oxygen uptake* ( $\dot{V}O_2$ ) is a measure of the rate of oxygen utilization for the production of energy. This measure is typically reported in units of liters per minute (L/min) or milliliters per kilogram body mass per minute (mL/kg/min). The latter provides for better comparison among individuals. Another commonly used measurement unit for oxygen uptake is the *metabolic equivalent* (MET). One MET is equal to 3.5 mL/kg/min, which is approximately the resting metabolic rate. *Maximal oxygen uptake* ( $\dot{V}O_{2\max}$ ) or maximal METs represents the maximal rate at which an individual can use oxygen. Classically,  $\dot{V}O_{2\max}$  is defined as the rate of oxygen uptake at which no further increase occurs despite an increase in dynamic work rate by the individual (see Fig. 61-2). The term *peak*  $\dot{V}O_2$  is often referred to when it is recognized that the highest attainable  $\dot{V}O_2$  is may not have been reached by the individual because of the mode of exercise being used, the testing protocol, physical limitations other than cardiorespiratory, or inadequate motivation. Clinically, assessment of peak or maximal  $\dot{V}O_2$  (mL/kg/min or MET units) is useful in assessing cardiorespiratory fitness as well as in counseling patients on

tolerance for undertaking home, leisure, or vocational activities within a reasonable work intensity.

## MUSCLE PHYSIOLOGY

### Structure and Function of Muscle

#### Morphology

Skeletal muscle is made up of structural and functional subunits as displayed in Figure 61-4 (12). The largest subunit of a muscle, from a morphologic standpoint, is the fascicle. The fascicle contains anywhere from one to hundreds of muscle fibers, the individual muscle cells. At each of these structural levels is a different connective-tissue covering.

Myofibrils are found within the muscle cells. The smallest functional subunit of the myofibril is the sarcomere. Sarcomeres are aligned end to end to form a myofibril. Myofibrils contain two basic protein filaments, a thicker one, called *myosin*, and a thinner one, called *actin*. These proteins are arranged in such a way as to give skeletal muscle its striated appearance. Sarcomeres run from one Z-line to the next Z-line.

**FIGURE 61-4.** Structural and functional subunits of skeletal muscle. (With permission from Lamb DR. *Physiology of Exercise: Responses and Adaptations*. 2nd ed. New York: Macmillan; 1984.)

**FIGURE 61-5.** Postulated mechanism of crossbridge formation and cycling by actin and myosin filaments. The head of the myosin filament is stippled and forms the crossbridge between the two filaments. Active sites on the actin (thin) filament are outlined by *broken circles*. **1:** No bonds between filaments. **2:** Initial attachment of myosin head to one of the active sites on the actin filament. This attachment takes place only in the presence of  $Ca^{2+}$  ions. **3:** Formation of strong actin-myosin bond. This process causes a conformational change in the angle of the myosin head, which produces a relative movement of actin and myosin filaments across one another. ADP and phosphate ions are lost from the myosin. **4:** If ATP is available, the actin-myosin bond can be broken. Subsequent hydrolysis of the ATP by the myosin ATPase returns the cycle to stage 1. If no ATP is available, the actin-myosin bond remains intact, as in muscular rigor. (From Gordon AM. Muscle. In: Ruch T, Patton H, eds. *Physiology and Biophysics*. Vol. IV. Philadelphia, PA: WB Saunders; 1982:170–260. Reprinted by permission of WB Saunders Co.)

### Sliding-Filament Theory

The primary function of muscle is to shorten and develop tension. The sliding-filament theory (Fig. 61-5) (13) provides an explanation of how muscle fibers shorten and so develop tension.

On stimulation from the motor axon, calcium ions are released from storage in the sarcoplasmic reticulum, exposing active binding sites on the actin and allowing actin-myosin cross-bridge formation. Once the actin-myosin bonds are formed, a conformational change in the angle of the myosin head occurs, causing the actin filaments to be pulled over the myosin filaments and to shorten the sarcomere.

For more shortening to occur, ATP is required to break the actin-myosin bond and allow binding of myosin to another actin site closer to the Z-line. The conformation change of the myosin head that is essentially the enzyme myosin ATPase then occurs, resulting in further shortening.

Relaxation of the muscle occurs when stimulation ends. This triggers the active pumping of calcium back into the

sarcoplasmic reticulum. The result is a loss of active binding sites on the actin, so that actin-myosin crossbridges are broken, and the muscle relaxes.

### Mechanical Model

Figure 61-6 shows a useful model to understand the mechanical properties of muscles (14). This model consists of the

**FIGURE 61-6.** Mechanical model of muscle consisting of a contractile element and two elastic elements. (From Roberts TDM. *Neurophysiology of Postural Mechanics*. London: Butterworth; 1978.)

**TABLE 61.3** Muscle Fiber Type Continuum Using the Myosin ATPase Classification System

Type I	IC	IIC	IIAC	IIA	IIAX	Type IIX
Highly oxidative High endurance High mitochondrial density Low contractile speed						Least oxidative High force Lower mitochondrial density High contractile speed

contractile element with both series and parallel elastic elements. The contractile element actively generates force and represents the interaction between actin and myosin filaments. The elastic elements are purely passive components acting as mechanical springs. The series elastic element represents the tendinous insertions of muscle, and the parallel elastic element represents the connective tissue surrounding the various sub-units of the muscle.

### Muscle Fiber Types

Skeletal muscles contain a mixture of muscle fiber types that can be distinguished by their physical and biochemical characteristics. At present, the most often-used classification system is the myosin ATPase histochemical profile for muscle. This array of fiber types allows classification of muscle fibers along a continuum from the most oxidative fiber to the least oxidative phenotype (Table 61-3). Muscle fiber types can be identified using histochemical or gel electrophoresis methods. Histochemical staining of the ATPases is used to separate fibers into type I (slow twitch), type IIA (fast twitch), and type IIB (fast twitch) forms. However, the work of Smerdu et al. (15) indicates that type IIB fibers contain type IIX myosin heavy chain (gel electrophoresis fiber typing). For the sake of continuity, and to decrease confusion on this point, most journals and scientists have now adopted the term *IIX* to designate IIB fibers. While type IIB muscle fibers are found in humans, they are very rare and are part of the rodent fiber array. Thus, a continuum of muscle fibers exists from the most oxidative type I to the least oxidative type IIX as shown in Table 61-3. A motor unit typically contains type I or type II muscle fibers, thereby giving it specific characteristics important to recruitment order and “size principle” whereby motor units are typically recruited from the low threshold to high threshold motor units that is related to the force production required by the external demands of the task.

Recognition that there may be differences in muscles dates back to observations that fowl has meat that is “red” and “white.” It has since been learned that the different properties of muscles extend beyond the muscle fiber to the level of the motor unit. Based on contraction speed following a stimulus to the nerve axon, two main categories of motor units can be distinguished—fast units and slow units. Peak tension and relaxation are achieved more rapidly for fast units than for slow units (Fig. 61-7). Units with a fast contraction time are composed of muscle fibers with relatively large fiber diameters and

are innervated by large, fast-conducting motor neurons. These units also have a larger number of muscle fibers. Compared with the slow units, the fast units produce higher tensions. These fast units are further subdivided into fast-fatiguable (FF) units, which fatigue relatively easily, and fast-fatigue-resistant (FR) units, which have a high resistance to fatigue, similar to the slow units.

Although the number of fibers per unit and the fiber diameter are larger with fast units, these factors do not fully explain the differences in force production of fast and slow units. It is thought that there are also differences in the mechanism of force production within the fibrils (16).

All fibers from a given motor unit have the same histochemical characteristics. Slow units innervate type I slow twitch fibers and these fibers are characterized by high activities of succinic dehydrogenase and nicotinamide adenine dinucleotide dehydrogenase, enzymes involved in the major pathways for oxidative metabolism. The type I fibers are also richly supplied by capillaries. As a result, these fibers are well suited for performance of low-intensity, long-duration activities.

Those fibers innervated by fast motor units (fast-twitch or type II fibers) have a high activity of myofibrillar ATPase, the enzyme that breaks down ATP to release energy for contraction. They also have a high capacity for anaerobic metabolism as demonstrated by the high levels of glycogen and

**FIGURE 61-7.** Schematic representation of rate of tension generation and force production with different fiber types. The speed of contraction and force are greatest for type II fibers.

phosphorylase. Phosphorylase is an enzyme that is involved in the breakdown of glycogen. As a result, these fibers are suited for performance of high-intensity, short-duration work. Hybrid subtypes exist linking the major fibers of I and IA and IX on a continuum from type I to IC to type IIC, IIAC to IIA to IIAX to IIX. With activation of the motor units, a transition of the ATPase isoforms will move from the type IIX to the type IIA subtype (17). The continuum of hybrids fibers goes from the most oxidative isoform type I to the least oxidative isoform type IIX. However, again, when a motor unit is activated, oxidative processes increase and exercise training will even leave type IIX fibers that remain with higher concentrations of oxidative enzymes. Thus, the transition to the primary fiber type as visualized by the histochemical staining is related to the oxidative status of the fiber while it keeps its characteristic size and function. Capillary development also follows this transition to greater density as oxidative needs increase. However, due to the fact that type I motor units are orderly recruited first in almost all activities and are involved for the repetitive endurance activities, their oxidative, mitochondrial, and capillary profiles are always greater than type II or fast motor units.

Again, there is a continuum of myosin ATPase within muscle fibers ranging from that found in the least oxidative type IIX fibers and extending to the most oxidative fiber, the type I fiber. It has not been shown that any type of voluntary physical training can change fiber types from type II to type I, or vice versa. In reality, a continuum of fibers, including hybrids expressing more than one type of myosin simultaneously, exists in humans, extending through types IIX, IIAX, IIA, IIAC, IIC, IC, and I. The difference in protein composition within human muscle fibers, compared with the less complex situation in animals, appears to be due to a more intricate regulation by the nervous system to achieve functional changes at the level of the contractile unit.

The advantage of having different types of muscle fibers within a muscle is that the characteristics of the muscle are extended beyond that of any single fiber type. It is the proportion of muscle fiber types within a muscle that gives muscles the properties that make them suitable for different functions.

## Factors Affecting Muscle Function

A number of factors affect muscle function. It is well recognized that these factors include the state of training and degree of fatigue of the muscle. The specific adaptations of muscle to exercise training and the relationship of fatigue with muscle function are discussed in later sections. In this section, the interaction of other muscular, neural, and mechanical factors affecting muscle function is discussed. The reader is also referred to Chapter 3: *Assessment of Human Muscle Function*.

### Muscular Factors Cross-Sectional Area

Muscle size is one of the most obvious factors affecting strength. In isolated as well as intact muscles, maximal strength is related

to the cross-sectional area of the muscle. This relationship probably is related to the greater quantities of actin and myosin, and therefore greater numbers of crossbridges that can be activated to produce force when the muscle is larger. Muscles can produce 10 to 20 N/cm<sup>2</sup> of cross-sectional area (18).

Numerous studies have demonstrated changes in muscle cross-sectional area that occur in conjunction with strength changes produced by resistance training or detraining. Nevertheless, strength and muscle cross-sectional area do not change in parallel. It is clear that the cross-sectional area of the muscle does not fully account for differences in strength among individuals.

### Muscle Fiber Type

As described earlier, the maximal force and the power generation of a muscle are related to the percentage of fast-twitch fibers. In other words, muscle that has a high percentage of fast-twitch fibers will generate a greater maximal force than the same-size muscle with a lower percentage of these fibers (19).

## Neural Factors

### Motor Learning and Recruitment

The importance of neural factors in affecting muscular strength has been recognized through the dissociation between changes in strength and muscle size during a strength-training program. The gains in strength during the first few weeks of such training occur without any change in muscle size (20,21). The general consensus is that these early changes reflect neural adaptations that may include improved muscle activation and improved task performance from motor learning and coordination (22).

### Inhibitory Reflexes

Neural factors may also play a role in inhibition of muscle contraction. A protective reflex mechanism is thought to operate through the Golgi tendon organs that may be of particular importance when large amounts of force are being generated (23,24). Reflex inhibition of muscle contraction can also result through other sensory nerve endings. For instance, it has been demonstrated that quadriceps muscle inhibition is mediated through afferent activity of intracapsular receptors (25). It is also likely that muscle contraction is inhibited through pain reflexes (26–28).

Protective reflex mechanisms are also thought to be involved in what has been called the *bilateral deficit*. The force developed during bilateral contractions of a given muscle group is less than the sum of the forces developed by each limb independently (29,30). Reduced motor unit stimulation is associated with this bilateral deficit (31).

It may be possible to reduce the influence of protective reflexes through strength training. Hypnosis was shown to increase maximal force produced during forearm flexion by 17% among non-resistance-trained individuals, whereas there was no significant change in a strength-trained individual (32). It was concluded that strength training may induce an

**FIGURE 61-8.** Schematic relationship between maximal muscular force and velocity of movement.

inhibition of the protective reflex mechanisms. Furthermore, the bilateral deficit has been shown to be reduced through training with bilateral contractions (33).

The protective reflexes may be reduced in another way. Strength of a muscle group is increased when its activity is immediately preceded by contraction of the antagonist muscle group (34). The precontraction is thought to reduce the neural protective mechanism, allowing a greater force production.

## Mechanical Factors

### Force-Velocity Relationship

The maximum force a muscle can exert depends on the speed at which it is contracting. The maximal isometric force of a muscle is always greater than the force that can be exerted during shortening, and the maximal force exerted during lengthening is always greater than that exerted during isometric contraction. This relationship is displayed in Figure 61-8.

It is thought that the shape of the force-velocity curve is explained on the basis of the sliding-filament theory of muscle contraction (16). During a maximal isometric contraction, all crossbridges are formed. However, during shortening, there is an increase in the rate of detachment of crossbridges and an increase in the number of attached crossbridges that exert negative force. The result is a decrease in the total force exerted when the muscle is shortening. During lengthening contractions, the rate of detachment of crossbridges is slower than during a shortening contraction at the same velocity. The effect is that crossbridges are forcibly detached, and so a greater force is produced compared with shortening contractions.

### Positive Versus Negative Work

Besides the difference in maximal force production through concentric and eccentric contractions, there is a difference in energy cost for performing work through concentric (positive work) and eccentric (negative work) contractions. The energy cost for negative work is dramatically less than that for performing the

**FIGURE 61-9.** Demonstration of the difference in energy cost between positive and negative work. The two subjects pedaled coupled bicycles with one pedaling forward (performing positive work) and the other providing the resistance as the cranks rotated backward (performing an equal amount of negative work). Graph inset shows the differences in energy costs across the examined power outputs. (From Cavanagh PR, Kram R. Mechanical and muscular factors affecting the efficiency of human movement. *Med Sci Sports Exerc.* 1985;17:326–331. Reprinted by permission of Williams & Wilkins. Figure based on data from Abbott BC, Bigland B, Ritchie JM. The physiological cost of negative work. *J Physiol.* 1952;117:380–390.)

same amount of positive work (Fig. 61-9) (35,36). This phenomenon is thought to be linked to the requirement for ATP for the detachment and resetting of the crossbridges in concentric work but not in eccentric work (Fig. 61-10) (37).

### Short-Range Stiffness

When a maximally activated muscle is forcibly lengthened, the force produced by the muscle is greater than that produced isometrically (see Fig. 61-8). However, the situation may be different when the muscle is contracting submaximally. Forced lengthening of a partially contracted muscle results in an initial resistance greater than that produced isometrically, but the resistance may then fall below that produced isometrically (38). This phenomenon is referred to as *short-range stiffness* and is thought to be accounted for as follows. The rapid rise in tension at the beginning of forced lengthening results from the stretch of attached actin-myosin crossbridges. The stiffness of the muscle is very high while the crossbridges are still attached. However, once the crossbridges begin to dissociate, it is thought that the formation of new crossbridges occurs more slowly in a partially activated muscle, and so the number of attached crossbridges and the force produced are diminished.

Short-range stiffness is important in the initial part of the response of a limb to a disturbing force. For instance, partial contraction of agonist and antagonist muscles about a joint

**FIGURE 61-10.** Schematic comparison of the crossbridge formation and cycling during concentric and eccentric work. ATP is required for the detachment and resetting of the crossbridges in concentric work but not in eccentric work. (From Cavanagh PR, Kram R. Mechanical and muscular factors affecting the efficiency of human movement. *Med Sci Sports Exerc.* 1985;17:326–331. Reprinted by permission of Williams & Wilkins. Figure based on data from White DCS. Muscle mechanics. In: Alexander RMcN, Goldspeak G, eds. *Mechanics and Energetics of Animal Locomotion*. London: Chapman and Hall; 1977:23–56.)

increases the mechanical stiffness of the joint and can provide considerable resistance to perturbing forces such as those that might be encountered while walking across a crowded room with a full glass. This same phenomenon may also play a role in protecting joints from traumatic forces.

### Muscle Orientation and Attachment

The distance a tendon is inserted from the axis of rotation affects the torque generated by that muscle. For a given tension developed by a muscle, a tendon insertion farther from the center of rotation will allow greater torque production, although angular range will be reduced (Fig. 61-11). This anatomic effect allows some muscles to be more suited for production of large forces than others. Small anatomic variations may also account for some of the performance differences among individuals.

### Length-Tension Relationship

The tension produced by a muscle is affected not only by the contractile elements but also by passive stretch of the elastic elements (see Fig. 61-6). When relaxed muscle is passively stretched beyond its resting length, tension progressively develops (Fig. 61-12) (39). Maximal contraction of the muscle

**FIGURE 61-11.** Schematic representation of the effect of tendon insertion site on excursion. The excursion from a more proximally inserted muscle may be double that of a more distally inserted muscle for the same amount of shortening. Whereas a tendon insertion closer to the center of rotation will allow greater excursion, torque production will be reduced for a given tension developed in the muscle.

at different lengths yields another length-tension curve. Subtraction of the passive tension from the total tension of the contracting muscle yields a closer representation of the actual tension produced by the contractile elements. The greatest tension generated by the contractile mechanism is at the resting length of the muscle, and the greatest total tension is at a length slightly longer than resting length.

The influence of length on the force produced by the contractile mechanism is related to the way in which the actin and

**FIGURE 61-12.** Length-tension diagram for passive stretch of an unstimulated muscle and total tension when the muscle is maximally stimulated. Active tension resulting solely from muscular contraction is obtained by subtracting the passive-stretch curve from the total-tension curve. Normal resting length is 100%. (Redrawn from Schottelius BA, Senay LC. Effect of stimulation-length sequence on shape of length-tension diagram. *Am J Physiol.* 1956;186:127–130.)

**FIGURE 61-13.** Relationship between sarcomere length and tension generation. The amount of overlap between actin and myosin filaments within each sarcomere is shown. The length of each sarcomere is given above, and the tension for each condition is shown below. Maximal tension is produced when there is the greatest overlap between filaments (points 2 and 3). Tension drops if the overlap is less or if the actin filaments contact each other. (Adapted from Gordon AM, Huxley AF, Julian FJ. The variation in isometric tension with sarcomere length in vertebrate muscle fibres. *J Physiol.* 1966;184:170–192.)

myosin filaments interact at the sarcomere level. Figure 61-13 shows the length-tension relationship for a single muscle fiber and the overlap of the actin and myosin filaments in a single sarcomere (40). As the overlap between actin and myosin increases, so does the tension production. Maximal tension is developed at lengths yielding maximal contact of actin and myosin filaments. As the sarcomere length decreases further, the actin filaments begin to overlap. It is believed that this interferes with crossbridge formation and causes a decline in tension development. Variations among sarcomeres and muscle fibers cause the length-tension curve to be more rounded for a whole muscle.

An example of the effect of muscle length on force production is apparent by the position of the wrist during a handgrip. While gripping, the wrist is maintained in extension by contraction of the wrist extensor muscles of the forearm. This

allows the finger flexor muscles to be at a more optimal part of the length-tension curve. In this way, a stronger handgrip is produced.

### Leverage Effect

The leverage effect relates to the mechanical advantage offered by the angle of tendon insertion. The torque produced by a muscle is dependent on the sine of the insertion angle. When the insertion angle is 90 degrees, the torque production is greatest for a given tension in the muscle.

Torque production is the net result of the length-tension relationship and the leverage effect. As a result of the force-velocity relationship, the torque production for a given movement is also dependent on the velocity of movement. Figure 61-14 displays an isokinetic torque curve for a

**FIGURE 61-14.** Real-time display of gravity-corrected torque and angular position during a knee extension-flexion isokinetic test. (From Baltzopoulos V, Brodie DA. Isokinetic dynamometry: applications and limitations. *Sports Med.* 1989;8:101–116.)

**FIGURE 61-15.** Optimal phenomenon in bicycling. Both seat height and pedaling frequency show an optimal point at which energy cost for producing a given power output is minimized. Maximal power output is also related to seat height by a parabolic curve. (From Cavanagh PR, Kram R. Mechanical and muscular factors affecting the efficiency of human movement. *Med Sci Sports Exerc.* 1985;17:326–331. Reprinted by permission of Williams & Wilkins. Figure based on data from Nordeen-Snyder K. The effect of bicycle seat height variation upon oxygen consumption and lower limb kinematics. *Med Sci Sports.* 1977;9:113–117; Hamley EJ, Thomas V. Physiological and postural factors in the calibration of the bicycle ergometer. *J Physiol.* 1967;191:55P–57P; Hagberg JM, Mullin JP, Giese MD, et al. Effect of pedaling rate on submaximal exercise responses of competitive cyclists. *J Appl Physiol.* 1981;51:447–451.)

movement commonly tested in the clinical setting (41). This figure demonstrates how maximal torque varies across movements when angular velocity is constant.

### Force Transmission

One way in which muscle force transmission is thought to vary without changing the tension developed in the muscle fibers is through a change in the elastic elements described in the mechanical model discussed previously (see Fig. 61-6). A decrease in the elasticity of these elements would allow a greater proportion of the force generated by the sarcomere to be transmitted to the skeletal system. With training, tensile strength of connective tissue is known to increase (42). Such changes may improve force transmission of a muscle.

### Elastic Storage and Recovery

Storage and recovery of elastic energy in the muscle-tendon unit occurs when an active prestretch immediately precedes a shortening contraction. This combination of eccentric and concentric contractions is a natural type of movement that has been referred to as the *stretch-shortening cycle* (43,44) and allows a greater concentric force production or power output than when the prestretch does not occur. In effect, this phenomenon modifies the length-tension curve so that at a given muscle length, the force produced is greater than that without the prestretch. The precise location and mechanism of the elastic storage is not clear, but it has been attributed to compliance of the crossbridges and connective tissue.

The greater force from a concentric contraction when immediately preceded by an eccentric contraction is a common feature of normal movement. An example of the use of elastic storage in this manner is the knee and hip flexion that occurs immediately before jumping. The most dramatic example of the use of elastic storage and recovery to affect the energy cost of movement is seen with the big red kangaroo. This animal

actually uses less energy per unit time as its speed increases as a result of greater use of elastic storage and recovery (45).

### Optimal Phenomena

The mechanical properties of muscles are important in accounting for what has been referred to as optimal phenomena (35). One such phenomenon is how the aerobic demand of riding a bicycle at a given power output is altered by the seat height. A height can be identified that minimizes aerobic demand and maximizes power output (Fig. 61-15) (46–48). Another example of optimal phenomena in cycling relates to pedaling rate. There is a pedaling frequency at which the aerobic demand to generate a given power output is minimized (see Fig. 61-15). Individuals also have a stride length that optimizes the aerobic demands of running (Fig. 61-16) (49) and a walking speed

**FIGURE 61-16.** Optimal phenomena in running. For a given running speed, there is a stride length at which energy cost is minimized. The freely chosen stride length is typically close to optimal. (From Cavanagh PR, Williams KR. The effect of stride length variation on oxygen uptake during distance running. *Med Sci Sports Exerc.* 1982;14:30–35. Reprinted by permission of Williams & Wilkins.)

**FIGURE 61-17.** Optimal phenomena during walking. A speed exists at which energy cost per unit distance is minimized. Energy cost is shown here in units of kilocalories per kilogram body mass per meter traveled. (From Cavanagh PR, Kram R. Mechanical and muscular factors affecting the efficiency of human movement. *Med Sci Sports Exerc.* 1985;17:326–331. Reprinted by permission of Williams & Wilkins. Figure based on data of Ralston JH. Energy–speed relation and optimal speed during level walking. *Int Z Angew Physiol.* 1958;17:277–283.)

that optimizes the aerobic demands for walking a given distance (Fig. 61-17) (50).

The critical observation to understanding these optimal phenomena has come from the work of Hill (51). He showed that the force-velocity curve could be used to generate a power-velocity curve that shows a point of optimality (Fig. 61-18). Then, by considering the energy cost of developing muscle tension under various conditions, a muscle efficiency-velocity

**FIGURE 61-18.** Optimal phenomena can be explained by derivations from the force-velocity relationship. The power-velocity curve is obtained from the product of force and velocity and demonstrates an optimal point. Energetic data allow generation of the efficiency-velocity curve, which also shows an optimal point. (From Cavanagh PR, Kram R. Mechanical and muscular factors affecting the efficiency of human movement. *Med Sci Sports Exerc.* 1985;17:326–331. Reprinted by permission of Williams & Wilkins. Figure based on Hill AV. The maximal work and mechanical efficiency of human muscles and their most economical speed. *J Physiol.* 1922;56:19–41.)

curve was generated that also showed a point of optimality. Thus, the changing of pedaling or stride rate can be considered as moving along the velocity axis of the muscle-efficiency curve. The interaction of the length-tension relationship is also important for some of the optimal phenomena.

### Muscular Fatigue and Endurance

Endurance and exercise intensity are related by hyperbolic functions, as demonstrated in Figures 61-19 and 61-20 (52–54). At high intensities, exercise can be continued for only short durations, whereas at low intensities, exercise can be continued much longer. The portion of the curve approaching the time axis is predominantly determined by the capacity for aerobic metabolism, whereas the portion of the curve approaching the intensity axis is predominantly determined by the capacity for anaerobic metabolism. The portion with greatest curvilinearity is determined by a combination of aerobic and anaerobic capabilities.

**FIGURE 61-19.** Isometric endurance as a function of percentage of maximal strength. (Adapted from Rohmert W. Ermittlung von erholungspausen für statische arbeit des menschen. *Int Z Angew Physiol.* 1960;18:123–164.)

**FIGURE 61-20.** Relationship of running speed to exercise duration for world record runs. (From Simonson E. Recovery and fatigue. In: Simonson E, ed. *Physiology of Work Capacity and Fatigue*. Springfield, IL: Charles C Thomas; 1971:440–458. Reprinted by permission of Charles C Thomas, Publisher, Ltd.; Springfield, Illinois. Figure based on data from Lloyd BB. World running records as maximal performances: oxygen debt and other limiting factors. *Circ Res*. 1967;20–21(suppl 1):1218–1226.)

Most exercise is performed at submaximal levels. At the onset of exercise, there is little sense of effort, but as the exercise is continued, performance is eventually reduced. This has led to the concept that fatigue is delayed in onset. However, maximal force generation and endurance capacity may begin to decline from the onset of even submaximal work with the same muscle group (Fig. 61-21) (55). Therefore, it may be preferable to think of fatigue as “any reduction in the maximal force-generating capacity” (56).

Another conceptual issue relates to the common belief that fatigue is a failure of normal physiologic function. Perhaps it is more appropriate to consider fatigue as a protective mechanism for survival. Fatigue prevents the onset of irreversible muscle rigor and protects the subsequent recovery process.

The causes of fatigue have received considerable attention but have not been clearly established. It is evident that multiple factors are involved, and the relative importance of each is dependent on the fiber type composition of the contracting muscle; the intensity, type, and duration of the contractile activity; and the individual’s fitness and motivation level. For instance, the fatigue experienced from high-intensity short-duration exercise such as weight lifting is dependent on factors different from those causing fatigue during low-intensity long-duration endurance exercise.

In daily life, a reduction in power output is frequently limited by central neural drive. Nevertheless, when motivation is high, the primary sites of muscular fatigue are thought to be within the muscle cell rather than the central nervous system or the neuromuscular junction. Specifically, it is thought that

**FIGURE 61-21.** Effect of leg cycling at different intensities and durations on maximal isometric knee extension force generation (A) and isometric knee extension endurance at 40% of rested MVC (B). Mean isometric strength and endurance in the rested state are displayed at R. (With permission from Hoffman MD, Williams CA, Lind AR. Changes in isometric function following rhythmic exercise. *Eur J Appl Physiol*. 1985;54:177–183.)

fatigue may result from disturbances in the surface membrane, excitation-contraction coupling, or metabolic events (57).

## ACUTE PHYSIOLOGIC RESPONSES TO EXERCISE

### Dynamic Exercise

Acute physiologic adjustments occur in most bodily systems with dynamic exercise. Collectively, these adjustments increase the availability of oxygen and nutrients to the active muscle cells, remove exercise-induced metabolic byproducts (e.g., carbon dioxide, lactate, heat), and maintain an appropriate internal milieu (pH, body fluid, etc.) for bodily function.

Dynamic exercise effort is typically expressed in either absolute units (e.g.,  $\dot{V}O_2$  in liters per minute) or relative units (e.g., percentage of an individual's  $\dot{V}O_{2\max}$ ). Absolute units provide a measure of work performed per unit time, whereas relative units reflect the degree of effort or how strenuous the exercise feels. Most physiologic changes with exercise are more proportional to relative than to absolute work units within a certain intensity range (58). This includes heart rate, ventilation, sympathetic/parasympathetic nerve outflow, circulating hormones, and core temperature. The one parameter that increases more in proportion to absolute work performed than relative intensity is cardiac output, which increases about 5 to 6 L/min for each rise in  $\dot{V}O_2$  of 1 L/min (59). Several factors may influence the magnitude of changes produced by dynamic exercise, such as body posture, age, gender, fitness level, disease state, and mode of exercise (e.g., leg vs. arm).

Many of the cardiovascular adjustments to dynamic exercise are regulated by changes in autonomic nervous activity outflow (60–63). Parasympathetic tone exists at rest, and its withdrawal at the onset of exercise allows heart rate to rise. When work intensity reaches about 50%  $\dot{V}O_{2\max}$ , parasympathetic withdrawal appears to be exhausted, and any further rise in heart rate is totally dependent on increased sympathetic nerve activity. In addition to increasing heart rate, sympathetic nerve activity increases myocardial contractility, mobilizes nutrients, influences several circulating hormone levels, and contributes to blood flow redistribution by vasoconstriction in inactive regions. Although muscle sympathetic nerve activity appears to increase in the active muscles, metabolic byproducts override this vasoconstriction effect to produce vasodilation. Control of the autonomic

nervous system during exercise originates from both central and peripheral receptors located in the motor cortex, ergoreceptors, and arterial and cardiopulmonary baroreceptors (63–65).

The rise in cardiac output (between about four- and sixfold to sevenfold at maximal effort) with upright leg exercise stems from a rise in heart rate (two- to threefold) and stroke volume (about 1.5- to 2-fold) (59,66). The rise in stroke volume results from increased myocardial preload and contractility (59,67,68). Preload increases as a result of enhanced venous return, which is brought on by venoconstriction and muscle contraction. An increase in contractility leads to more complete emptying of the heart (i.e., decreased left ventricular end-systolic volume), whereas an increase in preload increases left ventricular end-diastolic volume. The net effect is increased stroke volume.

Up to 80% of cardiac output can be distributed to the active muscles at maximal effort, compared with only about 20% of cardiac output being distributed to the muscles at rest. As illustrated in Figure 61-22, this marked blood flow redistribution is accomplished by arterial vasodilation in the active muscles and arterial vasoconstriction in other vascular regions (e.g., splanchnic, inactive muscle, renal) (8,59,69,70). Total systemic vascular resistance declines progressively with increasing work intensity. The precise mechanisms leading to vasodilation in the active muscle remain debatable but likely stem from changes in several local factors, including potassium, hydrogen ion, endothelium-relaxing factor, adenosine, osmolarity, and others (71,72).

The oxygen extraction rate is high within the active muscle. This, combined with the increased percentage of blood flow directed to the muscles, leads to an approximately

**FIGURE 61-22.** Schematic representation of the blood flow and distribution at rest and during maximal dynamic exercise. Exercise results in increases in blood flow to the exercising muscles and the coronary circulation but in reduced flow to the organs. Blood flow rates are indicated in milliliters per minute. (From Mitchell JH, Bloomqvist G. Maximal oxygen uptake. *N Engl J Med*. 1971;284:1018–1022. Reprinted by permission of *The New England Journal of Medicine*.)

threefold increase in arteriovenous oxygen difference at maximal exercise (59).

Systolic blood pressure rises progressively with increased dynamic workload, whereas diastolic blood pressure generally remains relatively unchanged. The net effect is a modest increase in mean arterial blood pressure (usually <20 mm Hg).

Ventilation rises linearly with  $\dot{V}O_2$  up to the anaerobic threshold (73,74). At and above the anaerobic threshold, ventilatory volume and carbon dioxide output ( $\dot{V}CO_2$ ) rise out of proportion to metabolism because of the  $CO_2$  produced from the bicarbonate buffering system (73,74). The changes in the relationship among  $\dot{V}O_2$ , ventilation, and  $\dot{V}CO_2$  with graded exercise testing are used to assess the anaerobic threshold noninvasively (73,74). The significance of determining the anaerobic threshold is that it provides an index of tolerance for sustained work and can be used in prescribing exercise intensity for aerobic training.

Considerable amounts of heat can be produced during exercise, as about 75% of the energy with aerobic metabolism is released as heat. Heat is transported to the skin surface via the cardiovascular system and dissipated via convection, radiation, conduction, and evaporation. Body core temperature rises with exercise, which aids in heat dissipation by increasing the heat flow gradient from the core to the skin (75,76). Reflex and locally mediated arterial vasodilation allow greater blood flow to be directed to the cutaneous vascular bed (63,77,78). This increased blood flow is accomplished in part by blood flow redistribution away from splanchnic and renal arterial vascular beds (63,78). Increased cutaneous venous compliance permits increased cutaneous blood volume and surface flow, which enhance heat dissipation at the skin surface (78,79). Increased cutaneous blood volume may lead to reduced venous return, left ventricular end-diastolic volume, and stroke volume. Heart rate can rise to compensate for the lower stroke volume as long as maximal heart rate is not attained. The sequence of events associated with heat stress during exercise is referred to as *cardiovascular drift* (77,79,80). Some cardiovascular drift typically occurs with prolonged (e.g., >60 minutes) exercise in a thermoneutral environment, although the magnitude is much greater in hot and/or humid environments because of the greater cutaneous blood flow and blood volume circulatory demands for heat removal. In a hot environment, the skin-to-environment temperature gradient for dissipating heat via convection, radiation, and conduction is reduced or even reversed if air temperature is greater than skin temperature. Similarly, the ability to dissipate heat via evaporation is proportional to the magnitude of the water pressure gradient existing between the skin and environment.

Sustained levels of high work intensity, especially when performed in combination with heat stress, can lead to high rates of sweat loss reaching 2 to 3 L/h. These rates of sweating can lead to dehydration and subsequent sequelae of decreased total blood volume, blunted cardiac output reserve, reduced thermoregulatory capacity, and decreased work tolerance (79,81–84). To help prevent serious dehydration, fluids should be consumed during sustained exercise. This should occur even

in the absence of thirst because a person can lose up to 2% of body water before feeling thirsty (77,81). A number of hormones involved in fluid regulation are altered during exercise, including increases in plasma renin activity, aldosterone, arginine vasopressin, and atrial natriuretic peptide (82,84–89).

### Static Exercise

The hemodynamic responses to static exercise are related to the percentage of maximal voluntary contraction (MVC) and the amount of muscle mass involved in the contraction (90). Increases in  $\dot{V}O_2$ , cardiac output, and heart rate are typically modest during static exercise compared with dynamic exercise (Fig. 61-23) (91). Additionally, total peripheral vascular resistance does not decrease, and stroke volume typically fails to rise as occurs with dynamic exercise (66). Blood flow through the active muscle is dependent on a balance between metabolically induced vasodilation and mechanical restriction of flow associated with contraction of the surrounding muscle. At high static efforts, blood flow through the active muscle is restricted and may be completely occluded (92). Reduced muscle blood flow relative to metabolic demands results in greater reliance on anaerobic metabolism and consequently earlier onset of fatigue than occurs with dynamic exercise. Mechanical and metabolic activation of skeletal muscle afferent nerve fibers during static exercise evokes a pressor response that leads to a significant increase in blood pressure, especially mean and diastolic blood pressures (93). For this reason, static exercise is often viewed as placing primarily a pressure load on the left ventricle, whereas dynamic exercise is viewed as placing more

**FIGURE 61-23.** Schematic comparison of hemodynamic responses to dynamic and isometric exercise. (Adapted from Hanson P, Rueckert P. Hypertension. In: Pollock ML, Schmidt DH, eds. *Heart Disease and Rehabilitation*. 3rd ed. Champaign, IL: Human Kinetics; 1995: 343–356.)

of a volume load on the left ventricle (94,95). Although initial studies suggested that the magnitude of the pressor response to static exercise was primarily related to the percentage of MVC, most (but not all) subsequent studies suggest that the amount of muscle mass used also impacts positively on the pressor response.

## HEALTH BENEFITS DERIVED FROM A REGULAR PROGRAM OF EXERCISE

Many health benefits have been reported with long-term, regular participation in physical activity. The optimal exercise prescription required for primary and secondary prevention of various disease states and for reducing overall mortality remains under investigation (96–99). For many years, the primary recommendation was to participate in an aerobic exercise program. More recently, many health organizations have revised their recommendations to acknowledge the benefit of physical activities that may not meet the aerobic criteria (96,100). The new recommendations encourage all people to accumulate a minimum of 30 minutes of at least moderate exercise most, if not all, days of the week (96,100). This 30 minutes can be accumulated from activities performed throughout the day, such as climbing stairs, gardening, and playing with children. This change in recommendations stems from (a) epidemiologic studies showing reduced mortality and/or morbidity in physically active people, including those who were not necessarily participating in an aerobic exercise program; (b) the failure of many people to adopt long-term aerobic exercise programs because of a variety of factors, including discomfort with higher-intensity effort; and (c) the low levels of physical activity required in our normal daily activities (96). Although the magnitude of benefits in terms of prevention is likely to be dose related, benefits are first contingent on long-term compliance with being physically active. As illustrated in the Activity Pyramid in Figure 61-24, the recent recommendations regarding accumulation of at least 30 minutes of moderate intensity of physical activity most, if not all, days of the week and the recommendations for aerobic and strength training provide a continuum of potential health and fitness benefits that can be used in prescribing exercise to people who differ in exercise readiness, health, exercise preferences, and goals. The concept is to individualize the exercise prescription to get more people physically active on a long-term basis to gain health benefits. Some of the health benefits that have been reported with regular participation in physical activity and/or aerobic exercise training are discussed next.

### All-Cause Mortality

Several studies indicate a reduction in all-cause mortality (101–103) with long-term, regular exercise participation. Although the minimal and/or optimal intensity, frequency, and duration for reducing mortality remain uncertain, most studies indicate an inverse linear dose-response relationship between the volume of physical activity and all-cause mortality

**FIGURE 61-24.** The Activity Pyramid is a model to facilitate education of the public about the adoption of a more active lifestyle. (Copyright 1997 Park Nicollet Health Source Institute for Research and Education. Reprinted by permission.)

(104). Some data suggest that the threshold level of physical activity required to have a measurable impact on mortality is an expenditure of 500 to 1,000 kcal/wk (104,105). Expending 1,000 calories per week in physical activity has been reported to reduce all-cause mortality by 20% or more (104,105). An inverse relationship has also been reported between laboratory-determined cardiorespiratory fitness and all-cause mortality, with an asymptote often reported at the upper level of the fitness distribution.

### Primary and Secondary Prevention of Cardiovascular Disease

Physical inactivity is considered a major risk factor for the development of cardiovascular disease (96,106–108). Many epidemiologic studies (105,109–114) have shown that people who are physically inactive have a higher incidence of heart disease than those who are physically active. Based on meta-analysis studies, the estimated risk of heart disease is approximately two times greater for inactive than for active people (115,116). In fact, this risk approaches that for hypertension and hypercholesterolemia. Because physical inactivity affects a greater number of people than any other single heart disease risk factor, the significance of physical inactivity is especially noteworthy.

In secondary prevention, meta-analysis of randomized trials of cardiac rehabilitation indicates a 20% to 25% reduction in mortality in those who participated in cardiac rehabilitation versus those who did not (117,118). The independent influence of exercise conditioning on mortality in this population remains uncertain, as several of these programs included education and advice on modifying other risk factors. For additional

information on secondary prevention of cardiovascular disease, the reader is referred to the Chapter, “*Cardiac Rehabilitation*”.

Reduced incidence of cardiovascular disease through physical activity certainly could have important societal implications. The estimated cost of cardiovascular diseases and stroke in the United States for 2002 was \$329 billion (119). If the prevalence rates remain the same, future health care costs could escalate with the projected rise in number of Americans older than 65 years. A regular program of exercise, combined with other healthy lifestyle habits, has tremendous potential in curtailing future health care costs. The nation’s health care goals for the year 2010, published in the Healthy People 2010 Program, are aimed at encouraging Americans to adopt healthier lifestyle habits, including greater participation in a regular program of exercise (120).

The mechanism by which physical activity reduces the risk of heart disease is not entirely clear. Some of the reduced risk stems from its impact on improving other risk factors, such as lipids, blood pressure, obesity, diabetes, and psychological stress (96,121). Physical inactivity remains, however, an independent risk factor for coronary artery disease after statistical adjustment for other risk factors.

### Blood Pressure Regulation

Hypertension is a potent risk factor for coronary artery disease, stroke, congestive heart failure, renal disease, and peripheral vascular disease. Both acute and chronic exercise can lower blood pressure (96,104,122–125). Meta-analysis of aerobic exercise training studies indicates an average decrease in systolic and diastolic blood pressures of 7 and 6 mm Hg, respectively, in those with hypertension and 3 and 2 mm Hg in systolic and diastolic pressures, respectively, in those with normal blood pressure with aerobic training (126). Debate still exists regarding the type of exercise program that produces the best blood pressure-lowering effect (126). Recently, aerobic exercise was reported to be associated with a more favorable blood pressure level than resistance exercise training among 10,000 participants evaluated from 1988 to 1994 in the Third National Health and Nutritional Examination Survey (127). Although there is some suggestion that moderate-intensity dynamic exercise may have a more favorable effect on blood pressure than high-intensity exercise, the data remain inconsistent (126).

### Lipid Management

Most studies indicate that aerobic exercise training lowers plasma triglycerides and may raise high-density lipoprotein (HDL) cholesterol (96,128–131). Elevated triglycerides and low HDL cholesterol are common lipid abnormalities in those with the metabolic syndrome that, in turn, is associated with increased prevalence of diabetes, hypertension, and coronary artery disease. Questions remain regarding the threshold of exercise needed to produce changes in blood lipids (130,132–135). Some data suggest a dose-dependent relationship (130,133–135), but Leon and Sanchez (129) stated that there was insufficient evidence to conclusively establish a dose-response relationship. Although lipid changes are associated with long-term participation in an

exercise program, a single bout of exercise can also produce acute positive lipid changes (104,136,137).

### Weight Control

Percentages of populations within industrialized countries who are considered overweight and obese are rising at epidemic proportions (138–140). In the U.S. population, more than 30% are considered obese (body mass index [BMI]  $\geq 30$  kg/m<sup>2</sup>) and another nearly 30% of women and 40% of men fall within the overweight category (BMI: 25 to 29.9 kg/m<sup>2</sup>) (139–142). Especially disconcerting is the nearly fourfold increase from 1963 to 2004 (<5% to <20%) in the number of obese children. Obesity carries many health risks, including heart disease, type 2 diabetes, hypertension, dyslipidemia, stroke, gallbladder disease, osteoarthritis, and certain types of cancer (139,143). When the BMI increases above 27, mortality increases sharply (143,144).

Most population studies show an inverse relationship between obesity and physical activity (96). Although many overweight and obese people periodically lose significant amounts of weight through diet alone, most regain this weight (145). In fact, many of these individuals undergo a weight loss/weight regain cycle (yo-yo weight pattern) several times in a lifetime. Rather than trying to lose weight through diet alone or exercise alone, a combination of moderate diet restrictions and increased regular exercise results in the best long-term weight management plan (146). Exercise seems to be especially important in long-term maintenance of weight loss (96,139,144). The most appropriate combination of intensity, duration, frequency, and mode of exercise to recommend for weight loss remains uncertain but will likely vary, depending upon percentage of body fat, age, and presence/absence of orthopedic or other medical complications (146–148). In addition to fat loss, increased physical activity may help maintain or increase lean body tissue during weight loss.

### Type 2 Diabetes Mellitus Prevention

Diabetes mellitus (DM) can lead to devastating microvascular complications and is a major risk factor for development of coronary artery disease (149). Morbidity and mortality are also higher in those with coronary artery disease when DM is present. Type 2 DM is increasing at an alarming rate in developed countries and is occurring at younger ages (138). Much of this increased incidence is attributable to lifestyle behaviors such as limited physical activity, excessive food intake, and greater prevalence of obesity.

Many studies have shown that exercise is beneficial for those with type 2 DM. A major benefit of exercise is that it increases insulin sensitivity. This effect is seen after a single bout of exercise as well as with chronic exercise. Exercise may act through several mechanisms to improve glucose regulation (104,150,151). Regular exercise may further benefit those with DM by improving body weight, blood pressure, and lipids.

Because of the devastating potential effects of diabetes, primary prevention of type 2 DM is important. Two recent studies (152,153) found that people with impaired glucose tolerance

(prediabetic state) reduced their incidence of DM during follow-up with a lifestyle diet/exercise intervention program designed to lose weight compared with those receiving normal care. This benefit was even more effective than that resulting from the administration of an oral antihyperglycemic agent.

The optimal intensity, frequency, and duration of exercise to recommend for protection against the development of type 2 DM or improved control of type 2 DM remain uncertain. Most studies showing benefits have used an aerobic exercise program. One study suggested that, for each 500 kcal/d increase in energy expenditure, the age-adjusted risk of type 2 DM could be reduced by 6% (154). Another study found that moderate-to-high-intensity exercise ( $\geq 5.5$  METs) performed more than 40 min/wk reduced the incidence of type 2 DM, whereas lower levels of exercise, regardless of duration, did not provide protection (155). These results suggest that a threshold of exercise must be achieved in terms of intensity and duration.

### Improved Psychological Well-being and Quality of Life

Mood state is improved immediately after aerobic exercise among regular exercisers (156). Furthermore, it is well recognized that regular physical activity improves general sense of well-being and quality of life (157–162). Changes that have been postulated to contribute to this include reduced psychological stress and improved tolerance for activities of daily living. In addition, regular exercise may help improve quality of life by protecting people from development of disabling diseases such as heart disease, diabetes, cancer, and cognitive decline as well as enabling people with diseases to regain functional work tolerance. Freedom from disease and ability to function independently into old age are important factors in quality of life. Shephard (163) estimated that remaining physically active into old age could allow one to maintain functional independence for 10 to 20 years longer than if one is inactive (Fig. 61-25).

### Maintenance of Bone Density

Osteoporosis is an important health problem. It causes considerable societal disability among the elderly and is a major

contributor to health care costs. Regular physical activity is recommended for enhancing bone density or reducing an age-related decline in bone density (164–172). Exercise habits during the peak bone-forming years may impact on bone density years later (166,171–173). The mechanism by which exercise impacts on bone density is incompletely understood, and the optimal intensity or threshold level of exercise for enhancing bone density remains uncertain. An interaction may exist between an adequate intake of calcium and exercise-induced benefits (174). Weight bearing appears to be an important stimulus, although muscle contraction without weight bearing may also promote bone density (164,165,167–169). In women, very high-intensity training can lead to amenorrhea and reduced bone density (175), an effect believed to be related to decreased estrogen levels.

### Increased Fibrinolytic Activity

Regular exercise may reduce the risk of thrombotic events by exerting an effect on coagulation and fibrinolytic factors such as lowering fibrinogen, plasminogen activator inhibitor 1, and platelet aggregation while raising tissue plasminogen activation (96,104,176–180). Most types of chronic exercise appear beneficial. However, acute strenuous exercise may increase platelet adhesiveness and aggregability in some individuals, more so in those who are sedentary than in those who are physically active (104,179,181).

### Decreased Inflammatory Marker

Associations have been reported between C-reactive protein and increased risk of cardiovascular disease. Regular exercise may have an anti-inflammatory effect, as evidenced by reduced levels of C-reactive protein with exercise training (180,182) as well as among those who are physically active (183).

### Improved Endothelial Function

Improved myocardial perfusion has been reported in patients with known coronary artery disease after a period of exercise training (184). One proposed mechanism is improved endothelial function (184). This may help attenuate a paradoxical

**FIGURE 61-25.** Demonstration of the effect of aerobic training on improving aerobic capacity and delaying its drop to a threshold where independent function can no longer be sustained. coronary arterial vasoconstrictor response observed in atherosclerotic segments and thereby improve coronary artery blood flow. Aerobic conditioning has been recently reported to help prevent and restore age-related declines in endothelial-dependent vasodilation in healthy people (185).

### Nonpharmacologic Antiarrhythmic Intervention

By enhancing vagal tone and reducing sympathetic activation, aerobic exercise training may exert an antiarrhythmic effect and thereby reduce the incidence of sudden death (186).

### Improved Sleep

Epidemiologic studies indicate that regular physical activity may be beneficial in improving sleep quality and reducing sleepiness during normal waking hours (187). The mechanism(s) by which exercise impacts on sleep remains uncertain.

### Possible Enhanced Immune Function

The impact of exercise training on the immune system remains uncertain. Some studies suggest moderate exercise training may enhance the immune system, whereas heavy training or arduous endurance events may depress the immune system. Much of this evidence stems from studies suggesting a protective effect against respiratory illnesses in those participating in regular moderate exercise training compared with sedentary individuals, but increased risk in athletes participating in high-level competitive events compared with sedentary individuals.

Although several studies have reported changes in many components of the immune system (e.g., cytokines, natural killer cell, immunoglobulin) with exercise and/or exercise training, further study is required to ascertain whether these changes impact significantly on immunity and, if so, whether they are beneficial or detrimental (188–192).

### Reduced Cancer Risk

A growing number of studies are showing that increased physical activity is associated with reduced risk of colon and perhaps

breast, prostate, and lung cancer (110,193–195). Some of the potential direct and/or indirect pathways by which exercise may be beneficial include reduced bowel lining exposure to mutagens via accelerated movement of food through the intestines, reduced breast tissue exposure to circulating estrogen, lowered circulating concentrations of blood insulin and growth factors, and improved body weight management. Many questions remain regarding the optimal dose of exercise for prevention of cancers, but, in general, exercise guidelines used for prevention of coronary artery disease are recommended (195).

## AEROBIC EXERCISE

### Physiologic Adaptations to Aerobic Conditioning

Aerobic exercise training produces many physiologic adaptations (Table 61-4). An important adaptation is increased work capacity, or  $\dot{V}O_{2\max}$ . Most studies indicate that sedentary people within diverse populations (age, gender, income, ethnic background, health status) will experience  $\geq 15\%$  improvement in  $\dot{V}O_{2\max}$  within 3 months of starting aerobic training (59,66,96,196,197). This increase is caused about equally by central cardiovascular adaptations that raise maximal cardiac output and peripheral adaptations that enhance oxygen extraction from the circulating blood (66).

Increased oxygen extraction with aerobic training stems from changes within the trained muscle, including increased capillary density, capillary-fiber ratio, tissue myoglobin, size and number of mitochondria per muscle cell, and respiratory enzyme capacity per mitochondrion (198–200). These muscular adaptations are believed to raise the anaerobic threshold and improve tolerance for sustained work.

The rise in maximal cardiac output with aerobic conditioning resides in increased stroke volume. Maximal heart rate does not rise with aerobic conditioning and may even be lower in well-conditioned endurance athletes than in sedentary individuals. The mechanism by which maximal stroke

**TABLE 61.4** Physiologic Adaptations to Aerobic Exercise Training as Observed in Resting and Exercise States

	Rest	Submaximal Exercise	Maximal Exercise
Aerobic power	No change	No change	Increase
Heart rate	Decrease	Decrease	Decrease
Stroke volume	Increase	Increase	Increase
Cardiac output	No change	No change	Increase

Ventilation	No change	Decrease	Increase
Arteriovenous $O_2$ difference	No change	Increase	Increase
Blood lactate concentration	No change	Decrease	Increase
Muscle blood flow	No change	Decrease	Increase
Splanchnic blood flow	No change	No change	Decrease
Systolic blood pressure	Decrease	Decrease	No change
Diastolic blood pressure	Decrease	Decrease	No change

volume increases with training is not entirely clear but involves increased cardiac preload and probably enhanced myocardial contractility and relaxation (66,201). Aerobic training causes an increase in total blood volume that partially accounts for the increased cardiac preload. The extent of cardiac adaptations appears to be related to such training factors as the length, intensity, duration, and mode of training and the time of life at which training was initiated.

A characteristic finding among elite male endurance athletes is an increased heart size (“athlete’s heart”) characterized by increased left ventricular end-diastolic volume and a proportional increase in left ventricular mass and normal wall tension (66,202). It is important to note that the enlarged heart of the athlete differs from the enlarged heart in hypertension and congestive heart failure (203). In the elite athlete, left ventricular hypertrophy is eccentric rather than concentric, and ventricular dilation is proportional to wall thickness. Indices of left ventricular diastolic function are typically normal or increased in athletes but impaired in pathologic states (204). The increased heart size in the athlete is believed to be important in permitting high levels of maximal stroke volume and thereby high functional work tolerance. Although highly trained women frequently show cardiac dimensional adaptations, they rarely demonstrate cardiac dimensional changes outside normal limits (205).

Physiologic adaptations to aerobic training may be restricted to the trained muscles when the amount of muscle mass used in the exercise is small (206–208). For instance, the physiologic benefits of upper-body endurance training appear to be primarily limited to the periphery (206,208). This is attributed to the lower blood flow and cardiac output requirements, which lessen the stimulus for central (i.e., heart) adaptations.

### Principles of Aerobic Conditioning

Intensity, duration, and frequency recommendations for aerobic exercise training have been previously provided by various groups. In 1998, the American College of Sports Medicine (ACSM) (209) recommended an exercise intensity range of 55% to 90% of maximal heart rate, or 40% to 85% of maximal reserve or heart rate reserve, with the lower-intensity levels being most applicable to individuals who are quite unfit. This typically translates to rating of perceived exertion (RPE) levels between about 11 to 12 (“fairly light”) and 16 (“hard”) (210,211). The RPE scale on which these values are based is shown in Table 61-5 (212). To achieve these recommended intensities, exercise modes that incorporate a large muscle mass such as walking, running, cycling, swimming, and cross-country skiing are optimal (211,213). Exercise durations of at least 20 minutes, and exercise frequency of at least three times per week was also recommended.

The ACSM has recently updated and clarified the earlier recommendations (100). This group now indicates that in order to promote and maintain health, all healthy adults need to engage in moderate-intensity aerobic physical activity for a minimum of 30 min/d on 5 d/wk or vigorous-intensity aerobic

activity for a minimum of 20 min/d on 3 d/wk. The activity can be accumulated in bouts of at least 10 minutes, and combinations of moderate- and vigorous-intensity activities can be used to meet these guidelines. They also point out that larger amounts of physical activity, including more activity at higher intensities, provide additional health benefits.

The optimal rate of progression to follow in implementing an exercise program depends on several factors, including the individual’s current activity levels, physiologic limitations, health, age, and exercise goals (99,209). The primary focus should be on adopting a progression that will result in long-term participation. Attempting to do too much too fast can lead to increased dropout rates as a result of perceived excessive discomfort and/or injuries. The ACSM suggests a progression rate subdivided into three phases, as illustrated in Table 61-6. Exercise programs can be tailored according to personal preferences by selecting various combinations of frequency, duration, intensity, and mode of exercise.

### Assessment of Aerobic Capacity

The  $\dot{V}O_{2\max}$  provides a reliable, reproducible measure of dynamic work capacity and cardiovascular fitness. It also provides information regarding medical prognosis in patients with heart disease and can aid in evaluating work resumption after recovery from a cardiac event (95,99,214). Many factors influence  $\dot{V}O_{2\max}$ , including age, gender, chronic levels of exercise, genetics, and disease (95,99). With increasing age,  $\dot{V}O_{2\max}$  declines about 5% to 10% per decade after age 20 (200,215). The age-related loss is attributed to several factors, including a progressive decline in maximal heart rate, body composition changes (e.g., loss of muscle), decreased physical activity, myocardial and vascular stiffening, and disease with increased age (200,215–217). Gender has an impact on  $\dot{V}O_{2\max}$ , with men having higher values than women when compared at a given age and activity level (95,200). The gender difference

**TABLE 61.6** Example of the Progression of an Aerobic Exercise Program for a Presumably Healthy Individual

Program Stage	Week	Exercise Frequency (sessions/wk)	Exercise Intensity (% Heart Rate Reserve)	Exercise Duration (min)
Initial stage	1	3	40–50	15–20
	2	3–4	40–50	20–25
	3	3–4	50–60	20–25
	4	3–4	50–60	25–30
Improvement stage	5–7	3–4	60–70	25–30

	11–13	3–4	65–75	30–35
	14–16	3–5	65–75	30–35
	17–20	3–5	70–85	35–40
Maintenance stage	21–24	3–5	70–85	35–40
	24+	3–5	70–85	35–40

From American College of Sports Medicine. *ACSM's Guidelines for Exercise Testing and Prescription*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000.

is largely attributed to the smaller muscle/whole-body weight ratio, lower hemoglobin, and smaller stroke volume in women (95). The high levels of  $\dot{V}O_{2\max}$  observed in elite endurance athletes (e.g., 70 to 85 mL/kg/min) compared with average young men (e.g., 40 to 50 mL/kg/min) probably stem from prolonged intense training plus genetic factors that enhance responsiveness to training (200,218,219).

The  $\dot{V}O_{2\max}$  can be mathematically defined as the product of maximal cardiac output and maximal arteriovenous oxygen difference. Considerable debate has existed over the years as to what physiologic system limits  $\dot{V}O_{2\max}$ . Most current evidence points to the cardiovascular system (62,200,220–222). A cardiovascular limitation could reside in maximal cardiac output, maximal muscle blood flow, or maintenance of an appropriate arterial perfusion pressure.

Aerobic capacity can be assessed through direct measurement of  $\dot{V}O_2$  during maximal exercise or through estimates from maximal or submaximal testing. Direct measurement of  $\dot{V}O_{2\max}$  is achieved with open-circuit spirometry techniques. In the clinical laboratory setting,  $\dot{V}O_{2\max}$  is more often estimated, based on the peak workload attained, than directly measured. If  $\dot{V}O_{2\max}$  is estimated, it is important to discourage significant handrail support with treadmill testing, as this can lead to a marked overestimation (99,223). Reasonably accurate estimates are possible with treadmill and cycle ergometer testing, as work efficiency is relatively constant among people with these testing modes. Conditions in which work efficiency is altered (e.g., walking with a prosthesis) can significantly reduce the accuracy of estimating  $\dot{V}O_2$  based on workload (224).

Treadmill or leg cycle ergometer testing is primarily used to evaluate  $\dot{V}O_{2\max}$ , although arm ergometry testing may be used for those unable to perform leg exercise. Among these test modalities,  $\dot{V}O_2$  at peak effort is generally highest with the treadmill, intermediate with leg cycle ergometer, and lowest with the arm ergometer (225–227). Differences in peak  $\dot{V}O_2$

between ergometers are largely attributed to differences in amount of muscle used.

Some individuals do not achieve  $\dot{V}O_{2\max}$  with symptom-limited testing, as the test is stopped before fatigue at the appearance of an adverse sign and/or symptom of another limiting factor (e.g., claudication). Lack of motivation is another common reason for not achieving a true  $\dot{V}O_{2\max}$ .

Supervision of exercise tests requires knowledge of when to stop a test for unreasonable risk and of which individuals should not undergo testing because of contraindications for exercise (99,228). Most clinical laboratories have established end points for graded dynamic exercise testing and contraindications for exercise testing (95,99,228).

A less formal method for assessing tolerance for daily activities or for estimating functional work tolerance is to measure distance walked/jogged in a set time period (e.g., 12 minutes) (99).

## STRENGTHENING EXERCISE

### Importance of Resistance Training

Strength development through resistance training is important for maintaining functional capacity, preventing and recovering from injuries, and improving sports performance (229). With the many physiologic conditions that promote catabolic breakdown of the muscle and connective tissues (e.g., aging, injury, disease), resistance training presents the only natural method to offset such wasting conditions.

### Physiologic Adaptations to Resistance Training Nervous System Adaptations

Maximal force production from a muscle requires the maximal recruitment of all motor units (230). It has been theorized that untrained individuals may not be able to recruit all motor units

voluntarily. Thus, part of the adaptation to resistance training is the development of the ability to recruit all motor units (22). Such neural adaptations are thought to be responsible for the increase in strength that precedes any increase in muscle size during the early phase of a resistance training program.

The central nervous system is also capable of limiting force by engaging inhibitory mechanisms that may be protective in nature. Resistance training may result in changes in the order of fiber recruitment or reduced inhibition (231).

### Muscle Enlargement

During heavy-resistance training, motor units containing both type I and type II muscle fibers are recruited and presented with a stimulus for adaptation. As a result, resistance training typically induces increases in the cross-sectional area of both type I and type II muscle fibers. This fiber hypertrophy is translated to increases in the cross-sectional size of the intact muscle, which can be observed after several months of training (232,233).

An upper limit of muscle cell growth has not been determined, but it has been suggested that an “optimal size” or ceiling of adaptation may exist for individual muscle fibers after a prolonged period of strength training (234). This upper limit may be due to a host of genetic factors, but it appears that the availability of myonuclei from satellite cells is important when cross-sectional increases skeletal muscle fiber area are greater than about 25% due to the need to maintain myonuclear domains (235,236). Alterations in the neural patterns of activation within the muscle to recruit all the available fibers may be of importance for the intact muscle to achieve maximal hypertrophy (237).

Muscle fiber hypertrophy is thought to occur through remodeling of protein within the cell and an increase in the size and number of myofibrils (238). Increases in the number of actin and myosin filaments along with sarcomere addition contribute to the increase in muscle fiber size. It has been suggested that the packing density of actin increases, but not myosin, as the contractile proteins are added to the outside of the myofibril without altering the crossbridge configurations (238,239).

The mechanisms and biochemical alterations that mediate the net changes in strength and muscle size observed with heavy-resistance training continue to remain an intense topic of study. Hormonal changes induced by resistance exercise appear to stimulate the uptake of amino acids, yet their incorporation into the contractile unit is not guaranteed. It is possible that contractile proteins accumulate in the muscle fiber either by an increased synthesis or by decreased rate of breakdown, or some combination of both. It is clear that muscle fibers are disrupted, and certain fibers damaged, with intense resistance exercise (240). The extent of this damage is less in trained individuals than in untrained individuals. The repair process of remodeling the muscle fiber may well involve a host of regulatory mechanisms (e.g., hormonal, cell signaling, and metabolic) interacting with the training status of the individual as well as the availability of protein.

Hyperplasia is considered to be a possible adaptive strategy (239), but the extent and frequency of this adaptive response remains a topic of debate. Interestingly, it has been speculated that most of the hyperplasia may well come from neural cell sprouting with the neural outgrowths taking on part of damaged fibers that have lost neural connections and would die without some type of reinnervation by a sprouting neuron (241). It may be that hyperplasia exists, but the magnitude of its contribution in even exceptional situations may not be great (<5%). In addition, hyperplasia may not occur equally in all individuals (238).

### Muscle Fiber Conversion

Transition within the muscle fiber subtypes from type IIX to type IIA appears to be quite typical with resistance training (17,242,243), and this conversion begins to occur within about 2 weeks of initiation of training (244). However, any transformation from type I to type II muscle fibers seems less probable (242,243).

It is not known to what extent this early conversion of muscle fibers may contribute to the initial changes in muscle strength. Nervous system alterations may have the most dramatic effects, mediating strength changes early in a training program, but other changes are taking place in the remodeling of the muscle fibers that may also affect strength.

### Other Adaptations Within the Muscle

It has been demonstrated that strength training can increase the activity of enzymes associated with the ATP-CP energy system (245,246), the anaerobic glycolysis system (245), and the aerobic system (245–247). However, increases in enzyme activity have not been a consistent finding among studies. The design of the strength-training program affects the magnitude of enzyme changes in the muscle. Changes in metabolic enzymes depend on the duration of individual sets rather than on the total amount of work performed. For practical application, normal heavy-resistance programs will have minimal effect on enzyme activities. However, a training program that calls for resistances that are tolerable for at least 30 seconds will most likely induce increases in the activity of muscle enzymes.

Muscular stores of ATP and CP and glycogen may increase with resistance training (248), although these changes are not always observed (249). Whether or not these changes occur with resistance training appears to depend on pretraining status, muscle group examined, and the type of program performed.

Improved capillarization has been observed with resistance training of untrained subjects (243,249–251), but the time required for this adaptation to take place can be greater than 12 weeks (249,252,253). It is thought that low-intensity/high-volume strength training is more likely to increase capillary density than high-intensity/low-volume training.

Myoglobin content in the muscle may be decreased following strength training (252). Thus, it has been postulated that long-term strength training may depress the ability of the muscle fibers to extract oxygen. Again, the initial state of training as well as the specific type of program that is used

may influence the effect of resistance training on myoglobin content.

Few studies have examined the effect of resistance training on mitochondrial density, but the observation of decreased mitochondrial density by one study (254) is consistent with the limited demands for oxidative metabolism placed on the musculature during most resistance-training programs. Yet, this report of decrease in mitochondrial density may be due to volume dilution in the analytical methods. With larger fibers, the relative number of mitochondria in the measured area decreases, when in fact absolute mitochondria and oxidative potential may well increase to address the greater oxidative needs of the activated motor unit (255).

### Body Compositional Changes

Body compositional changes can occur during short-term (6 to 24 weeks) resistance-training programs. Increases in fat-free mass normally mirror increases in muscle tissue weight, but because of concomitant decreases in fat, total body weight generally increases little over short training periods. The largest gains in fat-free mass that can be expected are a little more than 3 kg (6.6 lb) in 10 weeks of training (229). Though some athletes desire rapid gains in body weight, this is not possible to achieve through gains in muscle mass.

### Endocrine System Adaptations

It is apparent that the endocrine system plays a major role in the adaptational responses of skeletal muscle to resistance training (256). Serum testosterone concentrations have been demonstrated to increase in the first 6 weeks of resistance training and then to return to pretraining values (244). During the time that serum testosterone concentrations are elevated, significant changes in the type of muscle proteins (e.g., myosin ATPase hybrids, or myosin proteins) occur. Thus, the endocrine system appears to play an important role in the mediation of protein synthesis or reduced degradation that occurs during some phases of training.

### Adaptations to Connective Tissue, Bone, and Cartilage

The adaptations from resistance training allowing greater tension development by the muscles make it important for the strength of ligaments and tendons to also increase in order to avoid damage to these structures. It is now acknowledged that the dense fibrous tissues that make up tendons and ligaments are adaptable, but no research has been done specifically to examine the effects of heavy-resistance exercise on these structures (257,258).

Physical activity causes increased metabolism, thickness, weight, and strength of ligaments (42,259). Damaged ligaments regain their strength at a faster rate if physical activity is performed after the injury (42,259). Research involving laboratory animals has demonstrated that endurance-type training increases the amount of force necessary to cause separation at the attachment site of a ligament or tendon to a bone and the musculotendinous junction (42). There

is reason to believe that resistance training would produce similar results.

The connective-tissue sheaths that surround the entire muscle (epimysium), groups of muscle fibers (perimysium), and individual muscle fibers (endomysium) also adapt to resistance training. These sheaths are of major importance in the tensile strength and elastic properties of muscle, as they form the framework that supports an overload on the muscle. It has been found that muscle hypertrophy is accompanied by an increase in the absolute collagen content of these connective-tissue sheaths (260,261), but the amount of connective tissue appears to increase at the same rate as the muscle tissue (238).

Bone adapts to resistance training, but much more slowly than muscle, requiring 6 to 12 months for adaptations to be observed (262). Bone is sensitive to compression and strain. Such forces are common in resistance training and are related to the type of exercise used, the intensity of the resistance, and the number of sets performed. Training characterized by high-power exercise movements, heavy resistances, and multiple sets appears to be most likely to produce changes in bone metabolism.

Resistance training has been found to increase the thickness of hyaline cartilage on the articular surfaces of bone (263,264). One major function of hyaline cartilage is to act as a shock absorber between the bony surfaces of a joint. Increasing the thickness of cartilage could facilitate the performance of this shock absorber function.

### Peak Oxygen Consumption

The  $\dot{V}O_{2\max}$  is normally not considered to be significantly affected by heavy-resistance training (265,266). However, circuit weight training consisting of performing sets of exercises of 12 to 15 repetitions at 40% to 60% of the one-repetition maximum with short rest periods of 15 to 30 seconds between exercises may produce small increases in  $\dot{V}O_{2\max}$  (267). A resistance training program designed to increase  $\dot{V}O_{2\max}$  should consist of a high volume of training and relatively short rest periods between sets and exercises. Even then, the maximal increase in  $\dot{V}O_{2\max}$  brought about by resistance training is substantially less than the 15% to 20% increase associated with traditional aerobic training programs. Therefore, if a major goal of a training program is to increase  $\dot{V}O_{2\max}$ , some form of endurance training should be included in the program.

### Principles of the Exercise Prescription for Enhancing Strength

Program design is a highly individualized process based on a sound understanding of the basic principles of resistance training. Therefore, one must have a process that can be used to design a resistance training program based on the understanding of a specific paradigm that can be used to develop, prescribe, and modify a resistance training workout over time. The considerations in this program design process will be discussed.

### Program Choices

Desired gains of many individuals are often unrealistic and lead to nonadherence in exercise training when improvements do not meet expectations. Conversely, substantial improvements are evident in the early phases of training, but such rate of change cannot be expected to continue with long-term training. This is especially true in the rehabilitation setting, where dramatic changes are observed once fundamental organic healing has occurred to the contractile unit. As a result, designing resistance training programs that are both effective and realistic can be a challenge.

The program can only be considered appropriate if it meets the needs of the individual and the desired goals are achieved. Yet it should be recognized that a given training program may be effective for an individual at one time but not at another. Since the individual's goals and fitness may change over time, it is important to make effective adjustments in the exercise stimuli so that the desired adaptations may occur.

With all the potential for changes in the variables of a resistance training program, nearly an infinite number of programs can be designed. Nonetheless, an initial exercise prescription can be developed based on our scientific understanding, the rehabilitation or training goals, and the type of associated program elements (e.g., training load, number of repetitions) needed to stimulate a change. The training response should be monitored and the exercise protocol should be modified if the desired effects are not observed after a period of training has been completed. Each adaptation will take place on a different time line (e.g., neural factors responding rapidly and muscle protein accretion leading to muscle hypertrophy will take longer), so the expectations for change must be kept within the physiologic context of each variable's time course for adaptation.

Ultimately, some individuals may never be able to attain a high degree of improvement for a particular variable due to their inherent genetic limitations (e.g., large gains in muscle hypertrophy are not possible with low numbers of muscle fibers). Nevertheless, the program design can be adjusted over time to optimize each person's physiologic potential for a particular training goal. Individual differences in any adaptation to a resistance training program are what drive the need for individualized programs. The absolute magnitude of a response to the same training program will vary among individuals based on their genetic predisposition and how much training plasticity exists in a given variable at that point in time. Thus, general programs written for rehabilitation, fitness, sports, or other activities should be viewed only as a starting point for an individual. One must then work to match the program design and its training responses with the rehabilitative and training goals of the individual.

### Program Design Variables

The key to successful program design is the identification of specific variables that need to be controlled to better predict the training outcomes. In fact, one study showed that using a

personal trainer to better control the progression of intensity led to more optimal gains in strength, compared with allowing the average individual performing resistance training to make such decisions alone (268). This underscores that the most challenging aspect of the resistance training prescription is making decisions related to the manipulation of the program variables. The development of individual training goals for specific phases of cycles of training also becomes paramount in program design. Therefore, the dynamics of planning and changing the exercise prescription is vital for ultimate success of any resistance training program.

Understanding the factors that go into creating the training stimulus is crucial to the success of the process. The creation of an effective exercise stimulus starts with the development of a single training session directed at specific trainable characteristics (e.g., force production, power, hypertrophy). Over time, changes made in the program variables will create the progressions, variations, and overloads needed to observe physiologic adaptations and improved functional abilities.

### The Needs Analysis

A needs analysis is a process that consists of answering a series of questions that will assist in the design of a resistance training program (269). The major questions in a needs analysis are

1. What muscle groups need to be trained?
2. What are the basic energy sources (e.g., anaerobic, aerobic) that need to be trained?
3. What type of muscle action(s) (e.g., isometric, eccentric actions) need to be trained?
4. What is the prior injury history and what are the primary sites of injury for the particular activities in which the individual participates?
5. What are the specific needs for muscle strength, hypertrophy, endurance, power, speed, agility, flexibility, body composition, balance, and coordination?

### *Biomechanical Analysis to Determine What Muscles Need to be Trained*

The first question requires an examination of the muscles and the specific joint angles that need to be trained. This involves a basic analysis of the movements performed and muscles involved with an activity. The decisions made at this stage will help define the choice of exercises, which is one of the program variables.

Because the principle of specificity is a major tenet in resistance training, understanding exactly what movement one is trying to mimic during resistance training is an important aspect of program design. Such analyses will allow one to use specific exercises that require the proper muscles and actions to be used in a manner specific to the activity for which one is being trained.

Resistance training for any sport or activity should include full range-of-motion exercises around all the major body joints. However, training designed for improving specific movements should also be included in the exercise protocol to maximize

the contribution of strength training to function. The best way to select such exercises is to analyze the biomechanics of the activity and match it to exercises. The importance of movement-specific resistance training programs (e.g., functional training) has surfaced over the past decade and has led to the development of specific equipment (i.e., stability balls, wobble boards) and programs targeting core stability, rotational strength and power, balance, reaction, speed, acceleration, and agility (270).

The principle of specificity is an overriding rule in any of the choices made for the design of a resistance training program. Each exercise and resistance used in a program will have various amounts of transfer to another activity or sport. The amount of transfer will be related to the degree of specificity that can be achieved with the available equipment. When training for improved health and well-being, the specificity of the training will be related to picking the right exercises that can impact a given physiologic variable (e.g., bone mineral density). Other program variables (e.g., rest periods) will also interact to optimize the metabolic system for positive effects as well. Thus, each decision that is made for the choice of exercise will interact with other program variables to create an integrated stimulus of a specific workout protocol.

#### ***Determination of What Energy Sources Need to be Trained***

Performance of any activity, whether self-care, work, or sport, relies on varying proportions of the three energy sources (1). The energy sources to be trained have a major impact on the program design. Resistance training typically focuses on the improvement of the utilization of energy derived from the anaerobic energy sources (ATP-CP and anaerobic glycolysis systems). However, resistance training can contribute to improvement in aerobic training effects by its synergistic effects on reductions in cardiovascular strain, more efficient motor unit recruitment patterns, and improved blood flow dynamics (e.g., enhanced reperfusion of muscles, tolerance of higher pressure loads, and higher percentages of MVC before shutting down venous return) under work stress.

#### ***Determination of What Type of Muscle Actions Should be Used***

Decisions regarding the use of isometric, dynamic concentric, dynamic eccentric, and isokinetic modalities of exercise are important in the preliminary stages of planning a resistance training program for sport, fitness, or rehabilitation. The basic biomechanical analysis described earlier is used to decide what muscles to train and to identify the type of muscle action involved in the activity. Most resistance training programs use several types of muscle actions. For example, one factor that separates elite power lifters from less competitive power lifters is the rate at which the load is lowered in the squat and bench press. Elite power lifters lower the weight at a slower rate than less competitive lifters, even though the former use greater resistances. In this case, some eccentric training may be advantageous for competitive power lifters. In another

example, many holds in wrestling involve isometric muscle actions of various muscle groups. It has been seen that both isometric grip strength and “bear hug” isometric strength are dramatically reduced over the course of a wrestling tournament (271). Therefore, some isometric training may help in the conditioning of wrestlers. Similarly, improved isometric endurance for shoulder stabilization and elbow extension may enhance crutch use, and various functional activities in daily life, such as getting onto or off of a chair or toilet, require isometric strength. Thus, improvement in isometric endurance at high levels of force production may aid recovery and help performance.

#### ***Assessment of the Primary Sites of Injury***

It is also important to determine the primary sites for potential injury in a work or sport activity. Furthermore, it is important to understand the injury profile of the individual. The prescription of resistance training exercises will be directed at enhancing the strength and function of tissue so that it better resists injury or reinjury, recovers faster when injured, and reduces the extent of damage related to an injury. The concept of *prehabilitation* refers to preventing initial injury by training the joints and muscles that are most susceptible to injury in an activity. The prevention of reinjury can also be an important goal of a resistance training program. Thus, understanding the typical sites of injury for the activity (e.g., knee joints in alpine skiing or low back in construction workers) and the individual's prior history of injury can help in properly designing a resistance training program. Resistance exercise stress causes muscle tissue damage or disruption, which stimulates hypertrophy and is mediated in part by many of the same inflammatory, immune, and endocrine processes that are involved in the repair of injury. Resistance training most likely helps to condition and prepare these systems for more extensive repair activities needed for faster injury repair as well as less tissue damage due to stronger tissue components.

#### ***Determination of the Need for Various Components of Muscular Fitness***

Determination of the magnitude of improvement needed for variables such as muscle strength, power, hypertrophy, endurance, speed, balance, coordination, flexibility, and body composition is a very important step in the overall resistance training program design. It may seem reasonable to assume that a resistance training program should be designed to optimize all these variables, but that may not necessarily be the case. For example, many sports require a high strength-to-mass or a high power-to-mass ratio. In such a case, resistance training programs should be designed to maximize strength and power while minimizing increases in body mass. This is evident in sports that use weight classes such as weightlifting, power lifting, and wrestling and for those sports that require maximal sprinting speed or jumping ability (e.g., high jump, long jump) where increasing body mass may be detrimental to the maximal height or distance attained, as well as speed. In addition, some sports, such as American football, benefit from

increasing lean body mass, where the force of impact is greater for a given body mass, assuming power is increased accordingly. Thus, the need for these components of muscular fitness must be evaluated so that proper resistance training partitioning may be used.

### Program Design

After the needs analysis has been completed, a specific workout is designed that leads to the development of a training program. These workout sequences should address the specific goals and needs of the individual. Program variables serve as the framework of one specific resistance training session. Changes in the program variables will make up the progression plan for an entire training period. Periods of training are now planned over a training cycle, and “periodization” of training becomes a vital concept in the manipulation of the program variables in chronic program design (229,272). In the rehabilitation setting, such periodization may mean that focused strengthening exercises are shifted to more functional exercises emphasizing the development of muscular endurance. In addition, neuromuscular recovery is often a vital factor in the rehabilitation setting, and using the concept of periodized training will allow for variation in both the exercise stimuli and the planned recovery.

### Program Variables

A number of variables can be manipulated in any resistance training prescription (229). These program variables are capable of providing a general description of any single workout protocol.

### Choice of Exercise

As described in the needs analysis, the choices of exercises will be related to the biomechanical characteristics of the targeted goals for improvement. The number of possible angles and exercises are almost as limitless as the body’s functional movements. A change in angle affects which muscle tissue is activated. Using magnetic resonance imaging (MRI) technology, investigators have shown that the type of resistance exercise (relative to joint angle and loading method) alters the activation pattern of the muscle (273). Therefore, it is important to understand that if the muscle tissue is not activated by using the most appropriate resistance load (periodized loadings) or joint angles, the desired tissue may not be affected and therefore the optimal rehabilitation progression will not occur.

Exercises can be arbitrarily designated as *primary exercises* and *assistance exercises*. *Primary exercises* are the exercises that train the prime movers in a particular movement. They are typically major muscle group exercises (e.g., squat, bench press, hang pulls). *Assistance exercises* are exercises that train smaller muscle groups and aid in the movement produced by the prime movers (e.g., triceps press, bicep curls).

Exercises can also be classified as structural (i.e., multiple-joint) or body part (i.e., isolated joint). Structural exercises include those whole body lifts that require the coordinated

**FIGURE 61-26.** Subject performing a squat, which is an example of a structural (i.e., multiple-joint) strengthening exercise.

action of several muscle groups. Power cleans, power snatches, deadlifts, and squats are good examples of structural whole-body exercises (Fig. 61-26). Multiple-joint exercises are those that use more than one joint to perform the movement. An example is the bench press, which involves movement of both the elbow and the shoulder joints. Other examples of multiple-joint exercises include the lat pull-down, military press, and leg press.

Exercises that attempt to isolate a particular muscle group are known as body-part or single-joint exercises. Bicep curls, sit-ups, knee extensions, and knee curls are examples of isolated single-joint or body-part exercises (Fig. 61-27). Many assistance exercises may be classified as body-part or single-joint exercises.

Structural or multiple-joint exercises require neural communication between muscles and promote coordinated use of multiple-joint movements. This has recently been shown scientifically in a study that demonstrates that multiple-joint exercises require a longer initial learning or neural phase than single-joint exercises (274). It is especially important to include structural and multiple-joint exercises in a program when whole-body-strength movements are required for a particular activity. In fact, most sports and functional activities in everyday life depend on structural multiple-joint movements.

For individuals interested in basic fitness, structural exercises may only be advantageous when there is a limited amount of training time and it is necessary to train more than one muscle group at a time. The time economy achieved with

**FIGURE 61-27.** Subject performing a knee flexion exercise, an example of a body-part (i.e., isolated joint) strengthening exercise.

structural and multiple-joint exercises is an important consideration for an individual or a team with a limited amount of time per training session.

### **Muscle Action**

Whether the muscle action is performed concentrically, eccentrically, or isometrically has an influence on the adaptation to the resistance exercise. Greater force is produced during eccentric muscle actions with the advantage of requiring less energy per unit of muscle force (275–277). It has been known for some time that there is a need for an eccentric component to optimize muscle hypertrophy (242,243). This is why techniques such as *heavy negatives*, *forced negatives*, and *slow negatives* have been used by individuals (e.g., bodybuilders) to maximize muscle hypertrophy. With pure eccentric resistance exercise, especially in untrained individuals, delayed-onset muscle soreness (DOMS) can be more prominent than with concentric actions (278). In addition, performing a high-intensity training session or performing new exercises at novel angles can result in greater muscle soreness when an eccentric action is involved. Nevertheless, dynamic strength improvements and hypertrophy are greatest when eccentric actions are combined with concentric actions in a repetition (242).

Isometric muscle actions are less metabolically demanding and less conducive to hypertrophy than dynamic muscle actions (279,280). Isometric strength increases are specific to the joint angles trained (i.e., angular specificity) but have shown carryover of up to  $\pm 30$  degrees of the trained angle (281). However, the magnitude of carryover appears greatest at joint angles corresponding to greater muscle lengths (282). Dynamic and isokinetic muscle actions can improve isometric strength, but

not to the extent of isometric training itself, further supporting the concept of specificity (283,284). Interestingly, a major criticism of several strength training studies is that subjects were trained dynamically yet tested isometrically (285).

### **Order of Exercise**

Traditionally, it has been recommended that resistance training workouts sequence large muscle group exercises before the exercises involving smaller muscle groups. Exercising the larger muscle groups first may result in a superior training stimulus being presented to all the muscles involved. This is thought to be mediated by stimulating a greater neural, metabolic, endocrine, and circulatory response, which may augment the training effects of subsequent muscles trained in the workout. This concept was also used in the sequencing of structural or multiple- and single-joint exercises. In this system, the more complex multiple-joint exercises (e.g., power cleans) were performed initially followed by the less complex single-joint exercises (e.g., bicep curls). This sequencing rationale is that the exercises performed in the beginning of the workout require the greatest amount of muscle mass and energy for optimal performance (286). Thus, these sequencing strategies focus on attaining a greater training effect for the large muscle groups. If structural exercises are performed early in the workout, more resistance can be used due to a limited amount of fatigue.

Contrary to the preceding discussions pertaining to exercise order, different types of “pre-exhaustion” methods have been used by bodybuilders in the United States and by weight lifters in the former Soviet bloc countries in their training. These approaches reverse the order of the exercises so that the small muscle groups are exercised before the larger muscle groups, or a single-joint exercise (e.g., dumbbell flye) is performed before a multiple-joint exercise (e.g., bench press). It is theorized that the fatigued smaller muscles will contribute less to the movement, thereby placing greater stress or intensity on the large muscle groups. Nevertheless, the pre-exhaustion techniques do not appear to be as effective for maximizing strength as the traditional sequencing method (229).

Another consideration in the exercise order is placing exercises that are being taught or practiced (especially complex movements) in the beginning of the exercise order. For example, if an athlete was learning how to perform power cleans, this exercise would be placed in the beginning of the workout, so learning motor skills of an exercise would not be inhibited by prior fatigue.

The order of exercises used in various types of circuit weight training protocols is another issue. The issue relates to whether one follows a leg exercise with another leg exercise or whether it is appropriate to proceed to another muscle group. The concept of pre-exhaustion can come into play here. Arm-to-leg ordering allows for some recovery of the arm muscles while the leg muscles are exercised. This is the most common order used in designing circuit weight training programs. Beginning lifters are less tolerant of pre-exhaustion and arm-to-arm and leg-to-leg exercise orders or stacking exercises for a particular muscle group due to high blood lactate concentrations (10 to

14 mmol/L), especially when rest periods between exercises are short (10 to 60 seconds) (287,288). In contrast, stacking exercises is a common practice among elite bodybuilders in an attempt to bring about muscle hypertrophy.

For strength training, it is recommended that basic strength exercises such as the squat and the bench press be performed initially during the workout. Training for enhanced speed and power entails performance of total-body explosive lifts such as the power clean and the jump squats in the beginning of a workout. Bodybuilding entails performance of many exercises under various conditions where training through fatigue is paramount. Improper sequencing of exercises can compromise the lifter's ability to perform the desired number of repetitions with the desired load. Therefore, exercise order needs to correspond with specific training goals. A few general methods for sequencing exercises for both multiple or single muscle group training sessions are

- Rotation of push/pull exercises for total-body sessions.
- Rotation of upper-/lower-body exercises for total-body sessions.
- Large muscles before smaller ones.
- Multiple-joint exercises performed before single-joint exercises.
- Weak-point exercises performed before stronger ones.
- Olympic lifts before basic strength and single-joint exercises.
- Most intense exercises performed before least intense (particularly when performing several exercises consecutively for the same muscle group).

One final consideration for exercise order is the fitness level of the individual. As discussed earlier, training sessions should never be designed that are too stressful for an individual, especially a beginning trainee.

### **Number of Sets**

First, it should be noted that not all exercises in a training session need to be performed for the same number of sets. The number of sets is one of the factors in any volume-of-exercise equation (e.g., sets 3 reps). Typically, three to six sets are used to achieve the optimal gains in strength, and the physiologic responses appear to be different with three versus one set of exercises in a total body workout (289,290). It has been suggested that multiple-set systems work best for development of strength and local muscular endurance (291,292), and the gains made will be at a faster rate than gains achieved through single-set systems (293). In most training studies, one set per exercise performed at the 8 to 12 repetition maximum (RM) at a slow velocity has been compared with both periodized and nonperiodized multiple-set programs. In untrained subjects, several studies have reported similar-strength increases between single- and multiple-set programs, and some have reported superiority of multiple sets. Studies examining resistance-trained individuals have shown multiple-set programs superior for strength, power, hypertrophy, and high-intensity endurance improvements (292,294–297). Most studies of 14 weeks or longer

(especially in trained individuals) demonstrate the superiority of varied, multiple-set programs for long-term improvement. These findings have prompted the recommendation from the ACSM for periodized multiple-set programs when long-term progression (not maintenance) is the goal (298). No study has shown single-set training superior to multiple-set training in either trained or untrained individuals. Therefore, it appears that both programs are effective for increasing strength in untrained subjects during short-term training periods (i.e., 6 to 12 weeks), yet multiple sets may provide the advantage for upper body exercises during this early phase of training (299). However, some short-term and all long-term studies support the contention that higher volume of training is needed for further improvement and progression in physical development and performance (300). Still, the need for variation is also critical for continued improvement, and this includes the use of lower-volume training programs for certain phases of the overall training cycle. The key factor is the use of “periodization” of training volume rather than number of sets, which represents only one factor in a volume and intensity periodization model.

Considering the number of variables involved in resistance training, comparing single- and multiple-set protocols may be an oversimplification. For example, several of the previously mentioned studies compared programs of different set number regardless of differences in intensity, exercise selection, and repetition speed. In addition, the use of untrained subjects during short-term training periods has raised criticism (301), as untrained subjects have been reported to respond favorably to most programs (302). Part of this has evolved because of the popularity of a specific single-set program in which researchers desired to compare it with other protocols. The use of a single-set program may be effective for untrained individuals during the early phases for lower body strengthening (299,303). However, it appears that greater volume (within reasonable limits) is needed beyond this point in training to produce optimal improvements. In advanced lifters, further increases in volume may be counterproductive, but it appears that the correct manipulation of both volume and intensity produces optimal performance gains and avoids overtraining (304,305).

Multiple sets of an exercise present a training stimulus to the muscle during each set. Once initial fitness has been achieved, a multiple presentation of the stimulus (three to six sets) with specific rest periods between sets that allow the use of the desired resistance is superior to a single presentation of the stimulus. The concept that a muscle or muscle group can only perform maximal exercise for a single set has not been demonstrated. In fact, multiple sets at a 10 RM using the same resistance can be repeated with as little as 1 minute rest in highly trained bodybuilders (306) or athletes trained to tolerate short-rest-period protocols (295).

The importance of the exercise volume (sets  $\times$  repetitions) is a vital concept of training progression. This is especially true in individuals who have already achieved a basic level of training or strength fitness. The time course of volume changes is important to the change in the exercise stimulus in periodized

training. Use of a constant volume program may lead to staleness and lack of adherence to training. Ultimately, the variation of training volume (i.e., using both high- and low-volume protocols) to provide different exercise stimuli over long-term training periods will be important to provide rest and recovery periods.

The number of sets performed per workout for multiple-set programs is highly variable and has not received much attention in the literature. In general, the total number of sets per workout will be affected by (a) the muscle groups trained and their consequent size (e.g., large- vs. small-muscle-mass exercises); (b) intensity (fewer sets for high intensity and vice versa); (c) training phase (whether the goal is strength, power, hypertrophy, endurance); (d) training frequency and workout structure (e.g., total-body vs. upper/lower body splits vs. muscle group split workouts); (e) level of conditioning; and (f) use of anabolic drugs (which enable lifters to tolerate higher than normal training volumes). It is common to see resistance training programs incorporating anywhere from 10 to 40 sets per workout. The correct number is based on the individual and depends on the preceding factors.

### ***Rest Periods Between Sets, Exercises, and Repetitions***

An understanding of the influence that rest periods have in dictating the stress of the workout and influencing the amount of resistance has been a topic of study over the past 15 years. Rest periods between sets and exercises determine the magnitude of ATP-CP energy source resynthesis and the concentrations of lactate in the blood. The length of the rest period significantly alters the metabolic, hormonal, and cardiovascular responses to an acute bout of resistance exercise, as well as performance of subsequent sets (287,288,295,306,307). Kraemer (295) reported differences in performance with 3- versus 1-minute rest periods. All subjects were able to perform 10 repetitions with 10-RM loads for three sets with 3-minute rest periods for the leg press and bench press. However, when rest periods were reduced to 1 minute, 10, 8, and 7 repetitions were performed, respectively.

For advanced training for absolute strength or power, rest periods of at least 3 to 5 minutes are recommended for structural exercises (e.g., squat, power clean, deadlift) using maximal or near-maximal loads, whereas less rest may be needed for smaller muscle-mass exercises or single-joint movements. For novices to intermediate-level lifters, 2 to 3 minutes of rest may suffice for structural lifts, as loading used during this stage of resistance training appears less stressful to the neuromuscular system (i.e., advanced lifters require resistances closer to his/her genetic potential where maximizing energy stores is crucial to attainment of that level of strength). Robinson et al. (308) reported a 7% increase in squat performance after 5 weeks of training when 3-minute rest periods were used, compared with only a 2% increase when 30-second rest periods were used. Pincivero et al. (309) reported significantly greater strength gains (5% to 8%) when 160-second rest intervals were used compared with 40-second ones. Strength and power performance are highly dependent on anaerobic energy metabolism,

primarily through the phosphagen system. It appears that the majority of phosphagen repletion occurs within 3 minutes (310,311). In addition, removal of lactate and other metabolites may require at least 4 minutes (308). Therefore, performance of maximal lifts requires maximal energy substrate availability before the set with minimal or no fatigue. Stressing the glycolytic and ATP-CP energy systems may enhance training for muscle hypertrophy (e.g., bodybuilding). Thus, less rest between sets appears to be effective for hypertrophy, whereas the use of both types of protocols may be important for optimizing strength and size.

In studies by Kraemer et al. (287,288,307), a combination of workouts was used to compare the impact of rest changes on lactate responses. The 5/3 workout consisted of using a 5-RM resistance for all exercises with 3 minutes of rest between sets and exercises. The 5/1 workout consisted of using a 5-RM for all exercises with 1 minute of rest between sets and exercises. The 10/3 and 10/1 workouts consisted of using 10-RM with either a 3- or 1-minute rest between sets and exercises, respectively. Comparisons of the 5/1 to 5/3 and 10/1 to 10/3 demonstrated the dramatic effect rest periods have on blood lactate concentrations. Short rest periods significantly elevated blood lactate concentrations compared with longer rest periods. Comparisons of 5/1 to 10/1 and 5/3 to 10/3 demonstrated the effects on blood lactate concentrations of repetitions at an RM resistance and total work (repetitions  $\times$  resistance  $\times$  distance resistance moved) performed. These comparisons indicated that higher volumes of work (10-RM) resulted in higher blood lactate concentrations. The effect that rest periods between sets and exercises, and the total work performed have on blood lactate concentrations is similar for both genders.

These studies indicate that the heavier resistance does not necessarily result in higher blood lactate concentrations. It is the amount of work performed and the duration of the force demands placed on the muscle(s) that influence the blood lactate concentrations. In other words, to produce high concentrations of blood lactate the high-intensity-exercise stimuli must be maintained for a relatively longer time (>20 seconds) than for pure ATP-PC phosphagen metabolism. In addition, repeating the stimuli with limited rest continues to drive the accumulating amounts of lactate in the blood to higher levels. The classic 10 RM performed in a multiple-set fashion (e.g., three sets) provides for such stimuli (287). In addition, a significant amount of muscle mass (e.g., leg exercises vs. arm curls) must be stimulated. High force that produces a greater time under tension may also stimulate greater lactate responses than work-matched, higher-velocity, lighter-resistance, and higher-power protocols (312).

From a practical standpoint, it has been demonstrated that short-rest programs can cause greater psychological anxiety and fatigue (313). This might be due to the greater efforts, discomfort, muscle fatigue, and metabolic demands. The psychological ramifications of using short-rest workouts must also be carefully considered when designing a training session. The increased anxiety appears to be due to the dramatic metabolic demands characterized by short rest workouts (i.e., 1 minute

or less). Although the psychological demands are higher, the changes in mood states do not constitute abnormal psychological changes and may be a part of the arousal process before a demanding workout.

The frequent use of such high-intensity workouts with short rest periods and heavy loading should be slowly introduced into a training program to enable a gradual improvement in tolerance to increased muscle and blood acid levels (decreased pH), and improvements in acid-base buffer mechanisms (314). When such adaptations are vital to an activity (e.g., wrestling or 400- to 800-m track events), the progression of training protocols from long to short rest period lengths is important to improve function. Usually, such a program is performed within the context of a more classical strength/power training program for a sport (e.g., two high-lactate workouts and two strength-power workouts in a week cycle) or as a pre-season program for 8 to 12 weeks before the start of the sport season. Short rest period length is also characteristic of circuit weight training, but the resistances used are typically lighter (i.e., 40% to 60% of 1 RM are used) (267). This type of training session does not result in blood lactate concentrations as high as those of short-rest-period 10-RM sessions.

Lactic acid may not be the “bad guy” we have often thought it to be (315). Although it may contribute to fatigue, it can be used as a source of energy. Furthermore, it provides a relative comparison of the stress and accumulative utilization of the anaerobic glycolysis system. The type of training session, including rest periods, will determine to a great extent the amount of lactic acid that is produced and removed from the body. Recent studies have shown that elevations in blood lactate concentrations may be important for increases in muscle strength and hypertrophy (316,317). Thus, the role of lactic acid during resistance training appears to be important, depending on the rehabilitation or training goals.

If a particular needs analysis identifies lactic acid as the primary energy source, the rest periods may be gradually shortened to allow the buildup of blood lactate, thus encouraging an increased tolerance and buffering of more acidic conditions. This type of training design (particularly for preseason training) may allow better tolerance for such anaerobic athletes as wrestlers, sprinters (400 to 800 m), and basketball players. Other anaerobic athletes, such as baseball players, rely primarily on the ATP-CP energy system to perform their skills. Consequently, resistance training programs that elevate lactic acid concentrations may not be necessary to improve performance of such sports. Careful manipulation of rest periods is essential to avoid placing inappropriate and needless stresses on the individual during training. Furthermore, because of fatigue created by a high-volume, short-rest workout, it may be inappropriate to place such a workout immediately before a training session designed to develop skill in the sport or activity. Exceptions to this rule of thumb may be in sports such as wrestling, where all skills are performed under conditions of high lactate concentrations.

Training for improved local muscular endurance implies the individual (a) performs several repetitions (or long-duration

sets), (b) trains to and beyond the point of fatigue, and/or (c) minimizes recovery between sets (i.e., training in a semi-fatigued state). Therefore, many repetitions and shorter rest periods (30 to 90 seconds or less) for local muscular endurance training appear to be most effective (318).

The amount of rest taken between repetitions has only been partially addressed. Rooney et al. (319) had subjects train using 6 to 10 consecutive high-intensity repetitions or 6 to 10 repetitions separated by 30-second rest periods. They reported significantly greater strength improvement with consecutive repetitions (56%) than with extended rest between repetitions (41%). These findings demonstrate that fatigue may contribute to the strength training stimulus. However, if a high percentage of the peak velocity or power is desired for each repetition in the workout, longer rest periods with fewer repetitions for several sets may need to be performed. Future research will need to address this aspect of rest between repetitions, as the “quality” of each repetition begins to take on greater importance in producing gains in strength and power. Rethinking of the old “rest-pause” training system may be one of the new directions for research in optimizing quality of the training session. With new feedback systems on resistance exercise equipment allowing signaling of other performance factors beyond just lifting a weight, the quality of each repetition can be evaluated based on the percentage of peak velocity or maximal power. The concept of a quality repetition in a workout will start to see more scrutiny and evaluation. Interestingly, it remains to be determined where this “fatigue” stimuli and the later, more “full recruitment” stimuli requiring a longer rest period interface for optimal training effects. Most likely both styles of training may be needed to gain different aspects of strength, size, and power fitness.

### ***Resistance Used (Intensity)***

The amount of resistance used for a specific exercise is probably one of the key factors in any resistance training program (293). It is the major stimulus related to changes observed in measures of strength and local muscular endurance. When designing a resistance training program, a resistance for each exercise must be chosen. Either RM or the specific resistance that only allows a specific number of repetitions to be performed probably provides the easiest way to determine a resistance. Typically, one uses a training RM target (a single RM target such as 10-RM) or RM target zone (a range such as 3 to 5 RM). As the strength level of the lifter changes over time, the resistance is adjusted, so a true RM target or RM target zone resistance is used.

Research has supported the basis for an RM continuum (291,293,318,320). This continuum simply relates RM resistances to the broad training effects derived from their use. An inverse relationship exists between the amount of weight lifted and the number of repetitions performed. Several studies have indicated that training with loads corresponding to 1- to 6-RM was most conducive to increasing maximal dynamic strength (321,322). Although significant strength increases have been reported using loads corresponding to 8- to 12-RM

(244,295,323) and this load range appears most effective for increasing muscular hypertrophy (324), loads lighter than this (i.e., 12- to 15-RM and lighter) have only had small effects on maximal strength in previously untrained individuals (318). However, they have been shown to be very effective for increasing local muscular endurance (325). Contrary to early studies in resistance training, it appears that using a variety of training loads is most conducive to increasing muscular fitness as opposed to performing all exercises with a 6-RM load (326). Therefore, periodized training in which great load variation is included appears most effective for long-term improvements in muscular fitness.

Moving away from the 6-RM or less strength stimulus zone, the gains in strength diminish until they are negligible. The strength gains achieved above 25-RM resistances are typically small to nonexistent in untrained individuals (291,318) and may be related to enhanced motor performance or learning effects when they occur. Various individual responses due to genetic predisposition and pretraining status affect the training improvements observed. But after initial gains have been made as a result of learning effects, heavier resistances will be needed to optimize muscle strength and size gains.

Another method of determining resistances for an exercise involves using a percentage of the 1-RM (e.g., 70% or 85% of the 1-RM). If the trainee's 1-RM for an exercise is 100 lb, 80% of the 1-RM would be 80 lb. This method requires that the maximal strength in various lifts used in the training program be evaluated regularly. If 1-RM testing is not done regularly (e.g., each week), the percentage of 1-RM used in training decreases and therefore the training intensity is reduced. From a practical perspective, use of percentage of 1-RM determination for many lifts may not be feasible because of the amount of testing time required. Use of an RM target or an RM target zone allows the individual to adjust resistances in response to an ability to perform greater repetitions in order to stay at the RM target or within the RM target zone.

The use of a percentage of the 1-RM resistance is warranted for lifts related to the competitive Olympic lifts of the clean and jerk, snatch, and variations. Since these lifts require coordinated movements and optimal power development from many muscles to result in correct lifting technique, the movements cannot be performed at a true RM or to momentary failure. The reduction in velocity and power output experienced in the last repetition of an RM set is not conducive to such structural lifts. When determining the resistance for power movements, a percentage of the 1-RM loading should be used rather than failure to lift the weight or RM.

In two studies by Hoeger et al. (327,328), the relationship between the percentage of 1-RM and the number of repetitions that can be performed was studied in both trained and untrained men and women. It was demonstrated that this relationship varies with amount of muscle mass needed to perform the exercise (i.e., leg press uses more muscle mass than knee extensions). When using machine resistances with 80% of the 1-RM, previously thought to be primarily a strength-related prescription, the number of repetitions that could be performed

was typically greater than 10, especially for large-muscle-group exercises such as the leg press. The larger-muscle-group exercises appear to need much higher percentages of the 1-RM to keep them in the strength RM zone of the repetition continuum. Shimano et al. (329) examined this relationship using free weights in trained and untrained men. At 60% of 1-RM, significantly more repetitions were performed during the back squat than the bench press or arm curl by both groups of men. At 80% and 90% of 1-RM, there were significant differences between the back squat and other exercises; however, differences were much less pronounced than at 60% of 1-RM and these intensities were within the 5 to 10 RM zone needed for strength development. This was different from the machined based data of Hoeger et al. (327,328). No differences in number of repetitions performed at a given exercise intensity were noted between trained and untrained (except during bench press at 90% 1 RM). Thus, using percentages of the 1-RM are dependent upon exercise equipment (free weights vs. machines) and exercise choice, and the RM zone should be checked to be sure the percentage is yielding the proper number of repetitions to meet training related goals. Initial data in men appear to indicate that training status of the individual has a minimal impact on the number of repetitions performed at relative exercise intensity with free weights.

In a study by Kraemer et al. (330), it was shown that power lifters could lift 80% of their 1-RM in the leg press for 22 repetitions (e.g., 80% of the 1-RM equated to the 22-RM resistance) and the untrained controls could only perform 12 repetitions at 80% of their 1-RM (e.g., 80% of the 1-RM equated to the 12 RM). Such data, along with the data presented in the two important studies by Hoeger et al. (327,328), clearly indicate that the method used to determine the resistance to be used for specific exercises in a training program must be carefully considered for each muscle group and for each specific type of lift and the exercise mode used (e.g., free weight squat vs. leg press machine). In general, a certain percentage of the 1-RM with free weight exercises will allow fewer repetitions than the same percentage of 1-RM on a similar exercise performed on a machine. This is probably due to the need for greater balance and control in space when using free weights.

Charts have been developed to predict the 1-RM from the number of repetitions performed with a submaximal load or to help determine an RM (e.g., from 1 to 10) from the 1-RM resistance that can be lifted. Unfortunately, most of these charts assume a linear relationship between these variables, which is not the case. Thus, such charts and the resulting values should only be used as rough estimates of a particular resistance to use for an RM resistance or to predict an individual's 1-RM. A variety of prediction equations are available to predict 1-RM, but these equations have the same inherent weaknesses as the prediction charts.

The amount of weight lifted per repetition or set is highly dependent on other variables, such as exercise order, volume, frequency, muscle action, repetition speed, and rest period length (331). Altering the training load can significantly affect

the acute metabolic (332,333), hormonal (287,288,334), neural (231,335), and cardiovascular (336) responses to training.

The load required to increase maximal strength may depend on training status. A load of at least 45% to 50% of 1-RM is needed to increase dynamic muscular strength in beginners (337). However, greater loads are needed in more experienced subjects. Häkkinen et al. (335) reported that at least 80% of 1-RM was needed to produce any further neural adaptations during resistance exercise. Neural adaptations are crucial to resistance training, as they precede hypertrophy during intense training periods. Thus, it appears that a variety of loads conducive to increasing both neural function (i.e., increased motor unit recruitment, firing rate, and synchronization) and hypertrophy is most effective for strength training.

### ***Repetition Speed***

The speed used to perform dynamic muscle actions affects the adaptations to resistance training. Repetition speed is dependent on training loads, fatigue, and training goals, and has been shown to significantly affect neural (276,335), hypertrophy (338,339), and metabolic (340) adaptations to resistance training. Force production and repetition speed directly interact during exercise performance. Generally, force production is greatest at slower speeds and lowest during high-speed movements. This relationship is graphically represented as by the force-velocity curve discussed earlier in this chapter. The implications of the force-velocity relationship are that training at slow velocities with maximal tension will be effective for strength training and training with high velocities will be effective for power/speed enhancement. This generally is the case; however, an interaction between both extremes of the velocity spectrum may be most effective for both strength and power enhancement.

Generally, moderate-to-rapid speeds (i.e., 1 to 2 seconds concentric, 1 to 2 seconds eccentric) are most effective for enhancing gains in strength and power performances compared with slow speeds, which appear most effective for increasing local muscular endurance and isometric strength for a specific number of repetitions. LaChance and Hortobagyi (341) reported significantly greater average power, work, and total number of repetitions performed using a self-selected (rapid) speed, compared with 2-second concentric and 2- or 4-second eccentric repetition speeds. Thus, improving set performance (i.e., number of repetitions or load) may be best accomplished with use of moderate-to-fast speeds.

A distinction needs to be made when examining intentional and unintentional slow-speed repetitions. Unintentional slow lifting speeds are used during high-intensity repetitions (i.e., strength training) in which either the loading and/or fatigue are responsible for the longer repetition duration. For example, the positive phase of a 1-RM bench press and the last repetition of a 5-RM set may last 3 to 5 seconds (342). This may be considered slow by comparison; however, lifting the weight faster is not possible during maximal efforts. These types of unintentionally slow lifting speeds are crucial to maximal strength development.

Intentional slow-speed repetitions are used with submaximal loads, where the lifter has greater control of the speed. Keogh et al. (343) showed that the force produced during the concentric phase was significantly lower for intentionally slow (5-second concentric, 5-second eccentric) lifting compared with traditional (i.e., moderate) speed with a corresponding lower integrated electromyographic (IEMG) activity for the slow speed. This study shows that motor unit activity may be limited when attempting to intentionally lift slowly. In addition, the lighter loads required to lift slowly may not provide an optimal stimulus for strength enhancement. Hatfield et al. (344) demonstrated that when intentionally slow speeds (10-second concentric and 10-second eccentric) were used, a significant and dramatic reduction in the number of repetitions, power output, and force output that could be performed was observed making such programs less than optimal for typical strength training goals. Therefore, intentionally slow lifting appears to be most suitable for increasing local muscular endurance, where the time under tension is greater than moderate and fast speeds.

In comparison, both fast and moderate lifting speeds can increase local muscular endurance, depending on the number of repetitions performed and rest between sets. Training with fast speeds is the most effective way to enhance muscular power and speed, and is effective for strength enhancement (345) but not as effective for hypertrophy at slow or moderate speeds (335). High-speed repetitions impose fewer metabolic demands in exercises such as the leg extension, squat, row, and curl than slow and moderate speeds (340). In addition, training for power is best accomplished through lighter loads (30% of the 1-RM) performed at maximal speeds (<1:1.5 ratio) (346).

A popular technique used for both strength and power training is *compensatory acceleration* (347,348). Compensatory acceleration requires the lifter to accelerate the load maximally throughout the motion (regardless of momentum) during the positive phase, thus striving to increase bar velocity to maximal levels. A major advantage is that this technique can be used with heavy loads and is quite effective, especially for multiple-joint exercises (349). Hunter and Culpepper (350) and Jones et al. (349) reported significant strength and power increases throughout the range of the movement when compensatory acceleration was used, and the increases were greater than those for training with a slower speed (349).

### ***Rest Periods between Workouts (Training Frequency)***

The number of training sessions performed during a specific period time (e.g., 1 week) may affect subsequent training adaptations. Frequency also includes the number of times certain exercises or muscle groups are trained per week and depends on several factors, such as volume and intensity, exercise selection, level of conditioning and/or training status, recovery ability, nutrition, and training goals. Training with heavy loads increases the recovery time needed before subsequent sessions, especially for multiple-joint exercises (337). The use of extremely heavy loads (90% to 100% of 1-RM)

may require 72 hours of recovery, whereas low and moderate loads (60% to 85% of 1-RM) may require less recovery time (48 and 24 hours, respectively) (351). In addition, reduced frequency is adequate during maintenance training. Training 1 or 2 d/wk is adequate for muscle mass, power, and strength retention (337). However, this appears effective for short time periods, as such long-term maintenance training (i.e., reduced frequency and volume) may lead to detraining.

Heavy eccentric training requires greater recovery time between workouts. Loading during eccentric training may be substantially more than concentric (i.e., 120% to 130% of 1-RM). Studies show that eccentric exercise is more conducive to DOMS (278,352,353). Eccentric training causes greater muscle fiber and connective-tissue disruption, enzyme release, DOMS, and impaired neuromuscular function that limits force production and range of motion (354). Recovery times of at least 72 hours are required before initiating another session requiring several heavy sets or supramaximal eccentric lifts (351). Thus, frequency modulation is needed for heavy eccentric training. A recent study in untrained subjects compared frequencies of 1 d/wk to 2 or 3 d/wk (355). Each session consisted of seven sets of 10 1- or 2-second eccentric-only contractions for the quadriceps muscles. Both training groups showed improvement following training. However, the results showed that eccentric training once per week was effective for maintenance, whereas two times per week was more effective for strength increases. Thus, the inclusion of heavy eccentric repetitions may necessitate a change in frequency (or the muscle groups trained per session) to accommodate the greater muscle damage.

Numerous resistance training studies have used frequencies of 2 or 3 alternating days per week in untrained subjects (242,356). This has been shown to be a very effective initial frequency. If the resistance training is not excessive, only moderate amounts of delayed muscular soreness should be experienced 1 day after the session. Some studies have shown 3 d/wk to be superior to 2 d/wk (357), whereas 3 to 5 days were superior in other studies (358,359). The progression from beginning to more aggressive training does not necessitate a change in frequency but may be more dependent on alterations in other acute variables, such as exercise selection, volume, and intensity. However, it is common to see three or four training sessions per week among those individuals training more aggressively. Increasing training frequency allows for greater specialization (i.e., greater exercise selection per muscle group and/or volume in accordance with more specific goals). To achieve a higher frequency of training, more detailed workouts should be developed, as simply performing the same exercises four times rather than three times per week is not the optimal approach to increasing frequency. Programs should use exercises that involve similar muscle groups but use different angles for particular movements (referred to as *split programming*) (229). For example, a 4 d/wk routine that involves performing the bench press all 4 days would be better designed by having the individual perform a regular bench press on 2 days and an alternate type of bench press (e.g., incline bench press) on the other

2 days. Thus, split programming allows for more variety in the exercise choices, because of the increase in the number of training days available. In addition, total-body or split-body-part workouts have been used to allow more training variety. Both styles of training (total-body or split-body-part workouts) have been shown to produce improvements in muscle strength and size (360). However, it is recommended that similar muscle groups or selected exercises not be performed on consecutive days during split-routine workouts to allow adequate recovery and to minimize the risk of overtraining.

Training frequency for advanced or elite athletes may vary considerably (depending on intensity, volume, and training goals) and is typically greater than that in intermediate lifting. One study demonstrated that football players training 4 or 5 d/wk achieved better results than those self-selected frequencies of 3 and 6 d/wk (361). Weight lifters and bodybuilders typically use high-frequency training (i.e., four to six sessions per week). The frequency for elite weight lifters and bodybuilders may be greater. Double-split routines (i.e., two training sessions per day) are common (351,362,363) during preparatory training phases, which may result in 8 to 12 training sessions per week. Frequencies as high as 18 sessions per week have been reported in Bulgarian weight lifters (351). The rationale for this high-frequency training is that frequent short sessions followed by periods of recovery, supplementation, and food intake allow for high-intensity training via maximal energy utilization and reduced fatigue during exercise performance (337). Häkkinen and Kallinen (362) reported greater increases in muscle size and strength when training volume was divided into two sessions per day as opposed to one among female athletes. In addition, exercises performed by Olympic lifters (i.e., total body lifts) require technique mastery that may increase total training volume and frequency.

Elite power lifters typically train with frequencies of four to six sessions per week (364). The superior conditioning of these athletes allows them to tolerate such high-frequency programs. However, training at these high frequencies would result in overtraining in most individuals. It is important that the individual be able to tolerate the physical stress so that an overtraining phenomenon does not develop (365). The development of periodized training cycles uses variations in training frequency to alter the exercise stimulus and provide for recovery and enhance the exercise stimulus.

Using a training program of 3 days a week for all situations and sports is not ideal. It is the individual needs and goals that determine the amount of exercise required to increase a particular physiologic or performance variable. Progression in frequency is also a key component to resistance training. Frequency of training will vary, depending on phase of the training cycle, fitness level of the individual, goals of the program, and training history. Careful choices need to be made regarding the rest between training days. These choices are based on the planned progress toward specific training goals and the tolerance of the individual to the program changes made. If excessive soreness is present the morning after a training session, this may indicate that the exercise stress is too

demanding. If this is the case, the workout loads, sets, and/or rest periods between sets and training frequency need to be evaluated and adjusted.

The configuration of these variables results in the exercise stimulus for a particular workout. Workouts must be altered to meet changing training goals and to provide training variation. Within this paradigm for the description of resistance exercise workouts, careful control of various components can be gained in manipulating variables to create new and optimal training programs (366). Because so many different combinations of these variables are possible, an almost unlimited number of workouts can be developed. Understanding the influence and importance of each of the program variables in achieving a specific training goal is vital to creating the optimal exercise stimulus.

Each program must be designed to meet the individual's needs and training goals with recognition of the individual's initial fitness level. It is important to remember that evaluation of a fitness level (e.g., 1-RM strength test) is typically not done until it is known that the individual can tolerate the test demands so that the data generated are meaningful (367). One of the most serious mistakes made in designing a resistance workout is placing too much stress on the individual before it can be tolerated.

## FLEXIBILITY

### Importance

It is important to maintain a range of motion adequate to perform one's desired activities. Lost range of motion can interfere with such functional activities as ambulation, self-care, or attendant care. Severe restrictions in range of motion may even produce complications such as skin breakdown. Even relatively small reductions in range may result in biomechanical accommodations that place abnormal stress on tissues elsewhere in the body that can induce secondary problems.

Although it is clear that restoration and maintenance of a functional range of motion is desirable, the benefits from greater flexibility are not clear. Proponents of stretching have claimed numerous positive effects, including the prevention of musculoskeletal injuries and improved performance in sports, reduced postexercise muscle soreness, and improved general well-being. Nevertheless, the objective support for these claims is limited (368). Pre-exercise stretching has been demonstrated to have no effect on the development of DOMS (369). It has also recently been demonstrated that running economy may even be better among those who have some lower-extremity tightness (370,371). This has been suggested to be related to the ability to better use elastic storage and recovery and minimize the need for muscle-stabilizing activity.

Recent studies have shown that when strength and power performance are important, static and proprioceptive neuromuscular facilitation (PNF) stretching should not be done immediately prior to the event or training activity since performance will be impaired (372,373). Under such

circumstances, static stretching for improvements in flexibility should be done at the end of an exercise session as part of a cool down or at another time separate from the strength and power exercises.

### Factors Affecting Range of Motion

A number of factors can limit joint range of motion, including tightness of soft-tissue structures such as muscle, tendon, ligament, and joint capsule. Involuntary muscle contraction in the form of spasm can also restrict range. The bony contour of the joint is important in determining the full range of motion. When there is abnormal bone growth around a joint, range can be restricted. In addition, intra-articular loose bodies (e.g., bone or cartilage) and excessive fluid can restrict joint range of motion.

Range of motion varies widely among individuals. Regular activities using a full range of motion will help maintain range, but the maintenance of range of motion is specific to the joints that are used. For instance, an individual can have normal range in one joint but have severely restricted range in another. When connective tissue is not stretched, the collagen component gradually shortens. As a result, the periarticular collagen and the connective tissue of the muscle shorten. Furthermore, immobilization of a muscle in a shortened position also causes a decrease in the muscle length through a decrease in the number of sarcomeres in the muscle (374).

Age and sex also seem to affect range of motion. Women tend to have greater range of motion than men, and young people usually have greater range than the elderly. Tissue temperature is another factor affecting range of motion, with warm tissue having greater distensibility than cool tissue (375–377).

### Techniques to Assess Range of Motion

Range of motion may be assessed in various ways. Angle measurements can be made with a goniometer, electrogoniometer, or flexometer (358). Flexibility for some movements is also commonly assessed through distance measurements between specific reproducible reference points. One example of this technique would be the assessment of temporomandibular joint motion through measurement of the distance between the upper and the lower incisors.

### Methods to Improve Range of Motion

#### Techniques

Restoration of joint range of motion and soft-tissue extensibility can be achieved through the use of several different stretching techniques and modalities. The three general categories of stretching techniques include ballistic, static, and PNF procedures.

Ballistic stretching is characterized by repetitious bouncing movements, where the momentum of a moving body segment is used to generate forces producing a rapid stretch. Fast rates of stretching, as is the case with ballistic stretching, are not advisable, particularly during the early phases of rehabilitation. When fast stretch rates are used, greater tensions are developed,

and more energy will be absorbed within the muscle-tendon unit for a given length of stretch (378,379). As a result, there is a greater risk for injury with this type of stretching. Furthermore, ballistic stretching does not appear to be as effective in enhancing range as other methods of stretching (380,381).

Static stretching involves a slowly applied stretch that is held for several seconds. Proponents of this technique believe that the muscle stretch reflex is minimized through a slow, progressive stretch (382). Static stretching is generally easy to perform, can be done voluntarily or received passively by the individual, and has little associated risk of injury. Although the optimal time to hold a static stretch and number of stretches that should be performed is not known, experimental studies on animals suggest that most stress relaxation takes place during the initial 12 to 18 seconds and that there is little alteration in muscle-tendon unit lengthening after the fourth stretch (379).

Several stretching techniques use the principles of PNF that were developed by Kabat (383) to aid in the rehabilitation of injured World War II veterans. The concept of these stretching techniques is to enhance relaxation of the muscle to be stretched through reciprocal inhibition and the stretch reflex. The two most common PNF stretching techniques are the contract-relax technique and the agonist contract-relax technique. With the former, the muscle is passively stretched, then contracted for 6 to 8 seconds, and then relaxed and passively stretched further to an increased pain-free range. This process is repeated three to six times. Theoretically, the prestretch contraction of the muscle results in inhibition through Golgi tendon organ reflexes.

The agonist contract-relax technique is identical to the contract-relax technique except that the stretch is accompanied by a submaximal contraction of the opposing muscle to the one being stretched. This voluntary contraction of the opposing muscle theoretically results in reciprocal inhibition of the stretched muscle.

When able to participate, the patient can provide valuable feedback to ensure that appropriate positioning is used so that the desired tissues are being stretched. The patient should also understand that some discomfort may be required for adequate stretching, but prolonged poststretching pain is indicative of an overzealous approach. It also seems to be of considerable importance for the patient and the therapist to understand that the most rapid gains in range of motion will be achieved through regular stretching. In some cases, the performance of stretching exercises several times each day is desirable, but increases in range of motion can be achieved through three to five sessions per week (380,381).

### Modalities

Some modalities may be used to enhance range of motion. Because the distensibility of warm tissue is greater than that of cool tissue (375–377), heat is commonly used before stretching. Ultrasound is the best therapeutic modality for heating deep-lying tissues (384) and can be used effectively as a prestretching treatment when there are no contraindications for its use. One should also take advantage of the elevation in tissue temperature that can be achieved through exercise.

**FIGURE 61-28.** Effect of leg cycling at different intensities and durations on intramuscular temperature of the quadriceps at a depth of 3 cm. The mean resting value is represented at R. (With permission from Hoffman MD, Williams CA, Lind AR. Changes in isometric function following rhythmic exercise. *Eur J Appl Physiol*. 1985;54:177–183.)

For example, the quadriceps intramuscular temperature can be elevated by 2°C after 10 minutes of cycling at a moderate intensity (Fig. 61-28).

Simultaneous stretching and brief application of fluorimethane spray (stretch and spray) or passage of ice along the course of the muscle being stretched has also been advocated as a means to enhance the stretch of muscles (385). When an active trigger point is present, stretching may be enhanced by injection of a small amount of local anesthetic into the trigger point before stretching. The reader is referred elsewhere (385) for a description of the techniques for stretch and spray and trigger point injections.

## PROPRIOCEPTION

### Importance

Proprioceptive organs provide the central nervous system with information about the position and movement of body parts. Recent work has demonstrated the importance of proprioceptive sensation in the rehabilitation after injuries, and in understanding the etiologies and predisposing factors to injuries and reinjuries.

Decreased joint proprioception has been observed in patients with osteoarthritis, rheumatoid arthritis, and Charcot's disease and is believed to influence the progressive joint deterioration with these disorders (386,387). The risk of falling may also relate to proprioception as measures of postural sway have been demonstrated to relate to the falling risk (388–391).

Much of the work demonstrating the importance of proprioception in rehabilitation comes from the sports medicine literature. The importance of improving proprioception has been demonstrated by the finding of a significantly greater risk of sustaining an ankle injury during soccer among players with abnormal proprioceptive testing compared with those players with normal values (392). The successful return to sport after a ligament injury may be even more dependent on proprioception than on ligament tension (393).

### Factors Affecting Proprioception

Sensation of the position and movement of a joint arise from afferent information originating from muscles, joint capsules, ligaments, and skin. As a result, injuries or disease to these structures may affect proprioception. For instance, reduced proprioception has been shown to be associated with knee (394) and ankle (395–397) ligament injuries, rheumatoid arthritis (398), and osteoarthritis (386). The importance of muscle receptors in proprioception has been demonstrated through the finding of impaired reproduction of joint angle after fatiguing contractions of the associated muscles (399).

Disease of the neurologic system may also affect proprioception. Diabetics with cutaneous sensory neuropathy have been shown to have a significant loss of ankle joint proprioception (400). Decreases in proprioception have also been found with increasing age (386,398,401,402) and may be part of the normal aging process.

### Techniques to Assess Proprioception

Methods for accurate and objective assessment of joint movement and position perception have not been adequately developed for widespread clinical use. The most common clinical method of evaluating proprioception is a nonquantitative test of joint position perception consisting of the subject verbally describing the joint position after the examiner passively moves the segment into one of two or more predetermined positions (403). Another nonquantitative testing technique used in the clinical setting involves testing the ability of a person to return a joint to a predetermined joint position.

In the research setting, a number of techniques have been used in the evaluation of proprioception. These research techniques include using an isokinetic dynamometer to quantify angles during reproduction of a predetermined joint position (404,405), matching of joint position with the side contralateral to the one being passively moved or positioned (406–408), and measurement of joint movement perception threshold (400,404,409). Although not exclusively a measure of proprioception, other techniques that may provide related information about balance and coordination include measures of postural sway (410,411) and responses to perturbations that create sway (412).

### Techniques to Improve Proprioception

Proprioceptive exercises are performed with the goal of reducing the proprioceptive deficits that may have resulted through injury or disease. There is some evidence for the effectiveness of proprioceptive exercises in that it has been shown that the proprioceptive deficits present after ligament injuries can be reduced (413–415).

Classic lower-extremity proprioceptive exercises have used the tilt (teeter or wobble) board. Unidirectional boards may be used initially, followed by multidirectional boards. More functionally specific proprioceptive exercises can also be developed. These activities may include backward and sideways walking and running, or other agility drills.

It should also be noted that elastic bandaging (386) has been shown to improve position sense in those with impaired proprioception. This may be achieved through enhancement of the activity of the skin proprioceptors.

## THE EXERCISE PRESCRIPTION

### General Considerations

Appropriate exercise prescriptions should systematically and individually recommend physical activity to develop fitness, maintain health, and/or treat specific conditions. Basic components of an aerobic exercise prescription include exercise mode, intensity, duration, frequency, and rate of progression. Exercise sessions should begin with appropriate warm-ups and end with a cool-down; these periods of reduced intensity improve performance and likely decrease risk of injury.

Although the specific goals of an exercise program depend on the individual, basic exercise goals include (a) counteracting the detrimental effects of sedentary living or reduced activity (e.g., from disease or injury), and (b) optimizing functional capacity within the physical limitations of present medical conditions. Additionally, exercise training programs can provide valuable clinical information for the ongoing treatment of a patient. Using these basic goals as a foundation, an individual's specific health history, risk factors, behavioral characteristics, personal goals, and exercise preferences will shape and detail the exercise prescription.

### Risk Stratification

Exercise prescription for middle-aged and older people must consider the risk of cardiac complications associated with exercise. Well-controlled exercise presents very little risk, with a low incidence of sudden death (approximately one death per year for every 15,000 to 18,000 individuals). In people older than 35 to 40 years of age, incidents usually occur in the presence of coronary artery disease and vigorous exercise (416,417). Despite this minor risk, the benefits of exercise conditioning far outweigh the remote possibility of sudden cardiac complications (96,417–419). Furthermore, regular exercise likely protects against sudden death or myocardial infarction from strenuous physical activities (61,66,96,418).

**TABLE 61.7** Coronary Artery Disease Risk Factor Thresholds

Risk Factors	Defining Criteria
<b>Positive</b>	
Family history	Myocardial infarction, coronary revascularization, or sudden death before 55 years of age in father or other male first-degree relative (i.e., brother or son), or before 65 years of age in mother or other female first-degree relative (i.e., sister or daughter)
Cigarette smoking	Current cigarette smoker or those who quit within the previous 6 mo
Hypertension	Systolic blood pressure $\geq 140$ mm Hg or diastolic $\geq 90$ mm Hg, confirmed by measurements on at least two separate occasions, or on antihypertensive medication
Dyslipidemia	Low-density lipoprotein (LDL) cholesterol $>130$ mg·dL <sup>-1</sup> (3.4 mmol·L <sup>-1</sup> ) or HDL cholesterol $<40$ mg·dL <sup>-1</sup> (1.03 mmol·L <sup>-1</sup> ), or on lipid-lowering medication. If total serum cholesterol is all that is available use $>200$ mg·dL <sup>-1</sup> (5.2 mmol·L <sup>-1</sup> ) rather than LDL $>130$ mg·dL <sup>-1</sup>
Impaired fasting glucose	Fasting blood glucose $\geq 100$ mg·dL <sup>-1</sup> (5.6 mmol·L <sup>-1</sup> ) confirmed by measurements on at least two separate occasions
Obesity <sup>a</sup>	Body mass index $\geq 30$ kg·m <sup>-2</sup> , or waist girth $>102$ cm for men and $>88$ cm for women, or waist/hip ratio: $\geq 0.95$ for men and $\geq 0.86$ for women
Sedentary lifestyle	Persons not participating in a regular exercise program or not meeting the minimal physical activity Recommendations <sup>b</sup> from the U.S. Surgeon General's report
<b>Negative</b>	
High serum HDL cholesterol <sup>c</sup>	$>60$ mg·dL <sup>-1</sup> (1.6 mmol·L <sup>-1</sup> )

<sup>a</sup>Professional opinions vary regarding the most appropriate markers and thresholds for obesity and therefore, allied health professionals should use clinical judgment when evaluating this risk factor.

<sup>b</sup>Accumulating 30 min or more of moderate physical activity on most days of the week.

<sup>c</sup>It is common to sum risk factors in making clinical judgments. If HDL is high, subtract one risk factor from the sum of positive risk factors, because high HDL decreases the risk of coronary artery disease.

From American College of Sports Medicine. *ACSM's Guidelines for Exercise Testing and Prescription*. 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.

A clinical identification of coronary risk factors crucially guides program development. Table 61-7 displays the coronary artery disease risk factor thresholds. The ACSM considers the following risk categories (99):

*Low-risk* individuals are asymptomatic younger adults (men  $<45$  years of age, women  $<55$  years of age) who meet or exceed one risk factor threshold or less. These people can safely begin exercise programs without further assessment (Table 61-8).

*Moderate-risk* individuals are older individuals (men  $\geq 45$  years of age, women  $\geq 55$  years of age) or those who meet the threshold for two or more risk factors. These people require further assessment and a medical examination only if they intend to initiate an exercise program containing vigorous activities (i.e.,  $>60\%$   $\dot{V}O_{2\max}$ ).

*High-risk* individuals possess one or more signs/symptoms from Table 61-9 or have known cardiovascular (cardiac, peripheral vascular, or cerebrovascular), pulmonary (chronic obstructive pulmonary disease, asthma, interstitial lung disease, or cystic fibrosis), or metabolic disease (DM, thyroid disorders, renal, or liver disease). These people should complete a thorough medical examination and exercise test before starting any exercise program.

Cardiac rehabilitation programs safely and effectively initiate exercise for individuals recently suffering cardiac events (420). Surveys indicate low morbidity and mortality rates associated with supervised exercise programs (421–425). Although

**TABLE 61.8** Recommendations for Medical Examination and Clinical Exercise Testing Prior to Exercise Participation

	Low Risk <sup>a</sup>	Moderate Risk <sup>a</sup>	High Risk <sup>a</sup>
Moderate exercise <sup>b</sup>	Not necessary	Not necessary	Recommended
Vigorous exercise <sup>c</sup>	Not necessary	Recommended	Recommended

<sup>a</sup>See text for description of risk categories.

<sup>b</sup>Absolute moderate exercise is defined as activities that are  $\sim 3$  to 6 METs or the equivalent of brisk walking at 3–4 mph for most healthy adults. Nevertheless, a pace of 3–4 mph might be considered to be “hard” to “very hard” by some sedentary, older persons. Moderate exercise may alternatively be defined as an intensity well within the individual's capacity, one that can be comfortably sustained for a prolonged period of time ( $\sim 45$  min), which has a gradual initiation and progression, and is generally noncompetitive. If an individual's exercise capacity is known, relatively moderate exercise may be defined by the range of 40% to 60% of maximal oxygen uptake.

<sup>c</sup>Vigorous exercise is defined as activities of  $>6$  METs. Vigorous exercise may alternatively be defined as exercise intense enough to represent a substantial cardiorespiratory challenge. If an individual's exercise capacity is known, vigorous exercise may be defined as an intensity of  $>60\%$  of maximal oxygen uptake.

older data (424) estimated one cardiac arrest per 112,000 patient-hours, one nonfatal myocardial infarction per 294,000 patient-hours, and one death per 784,000 patient-hours, more recent data (423) present a much lower risk rate of one cardiac arrest per 1.3 million patient-hours. A 16-year assessment within one center (421) also highlights the continuing improvements in safety of cardiac rehabilitation, as investigators noted no substantial increase in the rate of adverse events despite including higher-risk patients.

Children and young adults rarely die during physical activity, but the infrequent deaths that occur generally relate to hypertrophic cardiomyopathy, coronary anomalies, and acquired myocarditis (96,426,427). Individuals with known congenital heart disease should remain physically active but refrain from vigorous and competitive athletics (96). Although some research indicates screening for cardiac abnormalities provides little benefit to healthy young people (426), a recent study noted the effectiveness of a nationwide preparticipation screening system in reducing sudden cardiovascular deaths of young athletes (428).

### Injury and Illness Precautions

All exercises carry some risk of injury, but individualizing the exercise prescription minimizes the chance of causing or exacerbating health problems. Characteristics of the activity (e.g., weight bearing vs. non-weight bearing, intensity, volume, and progression) and the exerciser (e.g., biomechanical abnormalities or previous injury) influence injury potential. Persons predisposed to musculoskeletal injuries (due to obesity, previous injury, or biomechanical abnormality) should avoid weight-bearing activities to reduce injury risk. Appropriate footwear and exercise progression also minimize the chance of injury.

Exercise also exerts a noticeable influence on immune function. Individual exercise bouts transiently impair immune status based on exercise intensity, duration, and nutritional status, but this acute response reverses with moderate chronic training; sensibly trained individuals demonstrate better

immune function and decreased risk of infection compared to sedentary counterparts (189,191,192). The stress imposed by extreme exercise training (increased volume, intensity, or both) likely predisposes the exerciser to infection and illness, making the relationship between training intensity and risk of illness a “J”-shaped curve (188,190). How exercise affects the progression of existing infectious diseases like viral respiratory infections is poorly understood. As myocarditis can develop when individuals exercise in the presence of such illnesses, individuals should avoid strenuous exercise when suffering from a fever or myalgia (429,430).

### Environmental Factors

Hot and/or humid conditions increase the physiological challenge and health risk associated with exercise. Combining exercise and environmental heat stress produces a competition for blood flow between active muscle (to deliver oxygen and nutrients) and cutaneous vascular beds (to dissipate heat), reducing exercise performance and/or thermoregulatory capacity (431,432). Decreases in total body water (i.e., hypohydration) exacerbate this situation (433–435). The exertional heat illnesses (heat cramps, heat syncope, heat exhaustion, and heat stroke) occur more frequently in competitive events than recreational exercise, as the drive to maximize performance can override normal signals to decrease exercise intensity. Wise race organizers minimize these potential health hazards by warning participants about environmental conditions, scheduling events during the least stressful times of day, offering appropriate aid stations on the course, and if necessary, cancelling the event (436).

During exercise in the heat, people should (a) monitor physiological markers of stress (heart rate and rating of perceived effort typically rise relative to heat load (77,80)), (b) monitor mental state (confusion, disorientation, and/or irrational behavior strongly suggests the presence of a serious heat illness (437)), and (c) attempt to minimize hypohydration by matching sweat loss with fluid intake (438,439). Additionally, anyone planning to compete in a hot environment should acclimatize before competition. Daily exercise in the heat for 7 to 10 days significantly improves performance and thermoregulation. These adaptations occur secondary to improved sweating (earlier onset and increased capacity), decreased loss of electrolytes, and increased blood volume. As a consequence, acclimatization reduces physiologic strain during exercise in the heat as evidenced by lower heart rates and core temperatures at similar exercise intensities (77). For further details, see the ACSM position stand describing heat illnesses during exercise (437).

In extremely cold environments, exercisers must protect against hypothermia and cold injuries to exposed skin (frostbite and frostnip). Cold injuries occur more infrequently than heat illnesses because exercise produces large metabolic heat loads, defending core temperature against all but the coldest temperatures. In most conditions, appropriately layered clothing and protection of sensitive areas (e.g., hands, feet, and face) allow exercise to continue comfortably. After repeated exposures to

a cold environment, the body does exhibit adaptations that enhance heat production or minimize heat loss; however, cold acclimatization causes far less dramatic physiological changes than heat acclimatization (434).

Exposure to moderate and high terrestrial altitudes also challenges exercise. Altitude exposure reduces work capacity because the lower barometric pressure directly translates to less available oxygen. This effect becomes noticeable at approximately 1,500 m; each additional 1,000 m of ascent further reduces exercise capacity by 6% to 10%. Available information suggests cardiac patients can safely exercise to at least moderate altitudes (440–444). Because altitude exposure limits exercise capacity, the absolute work intensity that elicits a prescribed index of myocardial work (i.e., rate-pressure product) decreases as altitude increases, suggesting heart rate and perceived effort provide more appropriate indices of exercise intensity than absolute work units at altitude. Similar to other environmental stressors, chronic exposure to altitude motivates physiological changes that benefit exercise performance (primarily increased oxygen-carrying capacity of the blood) and reduce the incidence of altitude-related illnesses (e.g., acute mountain sickness).

Air pollution can also detrimentally affect exercise performance. Several air pollutants (e.g., particulate matter, carbon monoxide, sulfur dioxide, nitrogen oxides, and ozone) negatively impact work tolerance or cardiovascular responses to exercise (445,446). Further, exercise-induced increases in pulmonary ventilation expose the exerciser to larger doses of pollutants than experienced at rest. As strong evidence now suggests a link between air pollution and cardiovascular disease (447,448), individuals should avoid exercising (a) in highly polluted areas or near traffic congestion, and (b) in environments where ozone reaches a critical threshold. These recommendations especially apply to those with coronary artery or pulmonary disease.

Other environmental stressors also impact certain exercises. For instance, unique terrain or wind might substantially increase physiologic demands (449,450) and require a reduction in absolute work rates. Additionally, exercise prescription for potentially unstable individuals must always consider the risk of falling.

## Equipment

Many specialized devices exist to develop strength, aerobic fitness, flexibility, and proprioception. Although clinics frequently house this potentially advantageous equipment, patients must possess all necessary equipment to complete their exercise programs outside the clinical setting. Fortunately, small modifications to most exercises reduce or completely eliminate equipment needs. For example, strength training could employ body weight, heavy household items, or elastic tubing for the resistance. Walking and running efficiently develop aerobic fitness (211) and require no equipment other than appropriate footwear. Additionally, some individuals might have access to community resources (e.g., swimming pool) or own specific exercise equipment. Regardless of the specific circumstances, prescribing

exercise that patients can readily complete increases compliance (see the following section) and program effectiveness.

## Compliance

The extent of the challenge in getting people to exercise is evident when considering that approximately one in four adults in the United States report no leisure-time activity, and less than half meet physical activity recommendations (96,100). Most teenagers do not participate in vigorous activities, and about 50% do not participate in physical education classes at school (96,96). Sedentary living occurs more commonly among Americans with less education and economic or social disadvantages (96,451). To achieve the exercise objectives established in the Healthy People 2010 Program, Americans must considerably change their physical activity participation. Although evidence suggests an improved public awareness of the benefits of regular physical activity, this awareness has not yet translated into substantial improvements in physical activity among sedentary individuals (452–455). The recent release of the Surgeon General's report on physical activity emphasizes the importance of increasing physical activity among all Americans (456).

When using exercise as a treatment, it is important for the patient to understand and accept that they are not a passive participant as is commonly the case in the classic medical model. This significant difference challenges many individuals, and exacerbates the compliance issue. Instilling a sense of self-involvement, an understanding of exercise fundamentals, and a basic idea how exercise may alleviate the patient's condition drastically improves compliance and exercise program success.

Patients who misunderstand the differences between exercises designed to develop strength, flexibility, and aerobic fitness are more likely to question the value of the exercise and less likely to complete the exercise correctly. For example, patients must comprehend that strength increases when muscles voluntarily contract against resistance and aerobic fitness improves when movement raises heart rate and ventilation. Regardless of the exercise, clinicians should (a) inform patients that success likely requires some discomfort, and (b) teach patients to recognize the difference between signs of exercise stress (e.g., increased heart rate and muscle soreness) and symptoms of overexertion or injury. Patients must especially comprehend these concepts during the initial few days of exercise program, when novel symptoms or DOMS occurs most frequently and discouragingly. Postexercise cryotherapy and reduced initial exercise intensities limit painful symptoms and DOMS; this attenuation of discomfort likely improves adherence when starting an exercise program. After these first few days, patients must also appreciate that adaptations resulting from an exercise program take time (usually a minimum of several weeks) and only occur with a commitment to a regular and consistent routine. The patient's personality, the rehabilitation setting, and the clinician-patient relationship all influence adherence rates (457). Of these, patient motivation most strongly influences success rate. Education, goal setting, and regular follow-up

(with appropriate exercise modification and progression) play important roles in developing and maintaining motivation.

Other than these general recommendations, three specific techniques maximize compliance. First, adherence improves when the program consists of activities the individual enjoys. Personal preferences relative to exercise mode, intensity, frequency, and duration should be considered (96). A second technique involves encouraging people to build physical activity into their normal routines and/or to participate in sport activities instead of (or in addition to) more traditional aerobic modes such as running or cycling. Increasing the exercise stress of typical home activities (e.g., using a walk-behind mower rather than a rider mower, walking stairs rather than riding the elevator) conveniently and inexpensively increases physical activity (96,458). When combined with a more traditional exercise program, home and recreational activities can add welcome diversity and significantly enhance adherence. Finally, attitudinal and behavioral factors within different population subgroups influence motivation for physical activity (96,459–461); individualizing exercise prescription based on ethnic background, socioeconomic status, gender, age, and disease also improves compliance. Individuals largely resist physical activities they consider inappropriate (e.g., because of age, gender, or mode), so practitioners should tailor the exercise prescription to clearly describe the value of the exercise or completely avoid undesirable exercises.

In summary, exercise compliance occurs most frequently when the individual perceives a benefit, enjoys (or minimally accepts) the activity, feels safe and competent, and recognizes the benefit of performing daily activities in ways that increase the physiological stress. Further benefits to compliance occur when exercise conveniently fits into the daily schedule and costs little (96). Much work remains to develop strategies for optimizing exercise compliance, especially among low physically active subpopulations such as the socioeconomically deprived (96,453,454).

## EXERCISE PRESCRIPTION IN SPECIAL POPULATIONS

### Considerations in Chronic Disease States

Exercise effectively assists in managing numerous medical and disabling conditions. Many individuals treated in the rehabilitation setting with exercise also suffer concomitant medical conditions or disabilities that affect the ability to perform and response to specific exercises. Accordingly, effective program design requires special considerations for people with disease or disability. In general, the exercise program must not interfere with the standard medical treatment and must vary according to the presence or severity of disease. The following text discusses important considerations for medical conditions and disabilities commonly encountered in rehabilitation settings. Several other specific chapters also discuss relevant disease states.

#### Cardiac Disease

Cardiac disease occurs commonly among individuals in the rehabilitation setting. Although cardiovascular disease generally

does not preclude exercise, those prescribing exercise must recognize the presence and extent of disease to design and initiate a safe program. Risk stratification (discussed earlier) significantly assists this process.

General guidelines for aerobic exercise apply to patients with stable cardiac disease. Patients with ischemic changes, angina, or arrhythmias during exercise should exercise at an intensity 10 to 15 beats per minute below the ischemic, angina, or dysrhythmic threshold (99). Individuals at high risk for exercise-induced cardiac emergencies (Table 61-10) require a more cautious application of exercise intensity and professional supervision, potentially including electrocardiographic and blood pressure monitoring. This population should complete gradual and prolonged cool-downs to reduce the risk of arrhythmias and postexercise hypotension.

Most low- to moderate-risk patients with stable cardiac disease can also safely perform and benefit from resistance exercise (462,463). Exclusion criteria precluding resistance training include congestive heart failure, severe valvular disease, uncontrolled hypertension, uncontrolled dysrhythmias, and other unstable symptoms (99). When monitoring exercise intensity during resistance exercise, rate-pressure product likely better indicates ischemic threshold than heart rate because resistance exercises frequently generate large blood pressures. Accurate determination of the rate-pressure product requires the measurement of blood pressure during muscular actions, as blood pressure decreases rapidly during relaxation.

#### Diabetes

Problems associated with diabetes (e.g., cardiovascular disease, peripheral neuropathy, peripheral vascular disease, autonomic

dysfunction, renal disease, and retinopathy) can significantly complicate the development of an exercise program. These complicating factors suggest all diabetics should complete a thorough medical examination before initiating an exercise program (99).

Because exercise increases glucose uptake independent of insulin, exercising diabetics frequently experience hypoglycemia (99). Excessive volumes or absorption rates of insulin cause hypoglycemia, and this may typically occur when patients inject short-acting insulin near active muscles. Type 1 (insulin-dependent or juvenile-onset) diabetics must therefore adequately regulate their insulin before initiating an exercise program. Table 61-11 lists important recommendations for all diabetics that minimize the risk of hypoglycemia.

Although general guidelines for aerobic exercise apply to most diabetics, several symptoms and conditions associated with diabetes pose unique challenges. The prevalence of peripheral neuropathy affecting the feet suggests diabetics should pay special attention to proper footwear, foot hygiene, and weight-bearing exercise (especially obese diabetics). Impaired sweating and polyuria-induced hypohydration limit thermoregulatory capacity, so diabetics should consider their exercise environment. Diabetics using  $\beta$ -blocking agents may not experience hypoglycemic symptoms and/or angina. Autonomic neuropathy and chronotropic insufficiency complicate the relationship between heart rate and exercise intensity, suggesting that diabetics suffering from these conditions should monitor and establish exercise intensity with perceived exertion. Finally, advanced retinopathy precludes exercise modes that cause excessive jarring or marked increases in blood pressure.

**TABLE 61.11 Recommended Precautions for Diabetics to Minimize the Risk of Hypoglycemic Reactions Associated with Exercise**

Monitor blood glucose prior to and following exercise, especially when beginning or modifying the program
Understand that a late-onset hypoglycemia can occur up to 48 h postexercise, especially when beginning or modifying the program
Know the signs and symptoms of hypoglycemia (e.g., drowsy, tremors, etc.)
Adjust carbohydrate intake or insulin injections prior to exercise based on blood glucose and exercise intensity. 20–30 grams of additional carbohydrate should be ingested if pre-exercise blood glucose is $<100 \text{ mg}\cdot\text{dL}^{-1}$
Avoid injecting insulin into exercising limbs; an abdominal injection site is preferred
When exercising late in the evening, an increased consumption of carbohydrates might be required to minimize the risk of nocturnal hypoglycemia
Postexercise hypoglycemia might occur in the hours following basic (not intense) resistance exercise for patients on insulin or oral hypoglycemic agents

From American College of Sports Medicine. *ACSM's Guidelines for Exercise Testing and Prescription*. 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.

## Obesity

Body mass varies according to only two factors: calories consumed (via nutritional intake) and calories expended (via basal metabolism, exercise, and thermic effect of food). Body mass decreases when caloric expenditure exceeds caloric consumption; a mild caloric restriction combined with regular exercise best accomplishes this goal (146,464). Additionally, increases in physical activity reduce the risk of associated comorbidities independent of body mass loss, making exercise important even if weight fails to change.

Overweight individuals generally lead sedentary lives and maintain negative connotations about exercise. A thorough exploration of these individuals' exercise histories crucially assists in combating psychological barriers and developing exercise compliance. The significant biomechanical stresses extra weight places on the body also predispose obese individuals to orthopedic injuries; exercises that minimize joint stress (e.g., walking, cycling, rowing, stair climbing, and exercise in water) attenuate these concerns.

## Arthritis

Exercise programs for individuals with arthritis vary according to disease state; when disease activity peaks, minimizing activity might avoid tissue damage. Programs for arthritis generally rely more heavily on shorter, more frequent exercise sessions, non-weightbearing or low-impact activities (e.g., swimming and cycling), and flexibility exercises to motivate positive adaptations while concurrently minimizing joint stress (99,465). Resistance training also optimizes strength, muscular endurance, and joint stability in this population.

## Peripheral Arterial Disease

Significant leg pain during physical activity (claudication) characterizes peripheral arterial disease, a condition typically associated with hypertension, hyperlipidemia, coronary artery disease, cerebrovascular disease, and diabetes. These frequent comorbidities generally place individuals with peripheral arterial disease at high risk for medical complications during exercise, suggesting these patients complete exercise testing before initiating a structured, medically supervised exercise program. Because treadmill walking and cycling cause significant pain, arm ergometry might most effectively achieve adequate myocardial stress during a descriptive test.

Of all exercise modes, walking best induces functional changes in those with peripheral arterial disease. Rather than continuous exercise, most experts (99,466) recommend intermittent exercise sessions; these repeated shorter exercise bouts induce symptoms that subside during brief, intervening rest periods. This method applies a suitable exercise volume while still accommodating claudication pain. Initial sessions of 35 minutes should progress to 50 to 60 minutes with the eventual goal of walking continuously for a similar duration. As functional capacity improves, increases in exercise intensity will induce beneficial central cardiovascular adaptations.

### Spinal Cord Injury

Spinal cord injury affects exercise capacity by altering the amount of functional muscle mass, compromising autonomic nervous control of cardioacceleration, redistributing blood flow, and limiting thermoregulation. Each issue affects exercise capacity, potential training adaptations, and safety during exercise. Despite these physiologic limitations, spinal cord-injured people safely participate in many activities (e.g., long-distance wheelchair propulsion, swimming, kayaking, and skiing) and commonly complete exercise programs of wheelchair propulsion or arm crank ergometry.

Depending on the characteristics of the lesion, spinal cord injury can limit functional muscle mass to the upper body. As the most effective aerobic exercise rhythmically recruits large muscle groups, this reduction in available muscle mass limits training-induced aerobic demands and therefore alters potential adaptations. Paraplegics can exercise intensely and adapt to exercise training (as demonstrated by the clearly positive effect of upper body endurance training on peak and work capacity during exercise), but most adaptations occur peripherally (206,208). In other words, spinal cord injury might severely limit the adaptive potential of central cardiovascular structure and function. Recent research suggests several techniques, including lower-body compression (467–469), functional electrical stimulation of the paralyzed lower limbs (470,471), or supine body position concomitant with upper-body exercise (472), might enhance venous return and cardiac output, thereby increasing the opportunity for central training adaptations.

Complete spinal cord lesions also affect the autonomic nervous system. Loss of sympathetic cardiac innervation from lesions above the sixth thoracic vertebra can limit maximal heart rate to 110 to 130 beats per minute (473). Lesions at the cervical and thoracic levels can impair control over regional blood flow during exercise, causing venous blood pooling in the legs and consequently reducing cardiac preload. As a result, stroke volume and cardiac output at a given oxygen uptake tend to decline in those with spinal cord injury (474,475). Furthermore, the loss of sympathetic nervous control over vasomotor and sudomotor responses of the insensate skin impairs thermoregulation (476).

Individuals with spinal cord injury should complete exercise testing before initiating an exercise program for two reasons in addition to screening for coronary artery disease. Testing also helps identify cardiovascular issues that might otherwise remain undetected because some quadriplegics lack classical symptoms of angina pectoris (as most cardiac visceral afferents enter the spinal cord at the upper thoracic levels). Additionally, exercise testing can identify and assist in the treatment of exercise-induced hypotension. Assuming the prescription accounts for these potential autonomic, cardiovascular, and thermoregulatory conditions, the intensity and duration guidelines for cardiovascular training in the apparently healthy appear reasonable for the spinal cord injured (473). Overall risk of serious problems from participating in appropriately structured exercise programs appears minimal for the spinal cord injured.

### Postpoliomyelitis Syndrome

Although many professionals feared those who suffered postpolio sequelae might experience overuse-induced muscle weakness with exercise, most evidence suggests these individuals can safely exercise without adverse effects. Individuals with postpolio sequelae generally respond to endurance (477–480) and resistance (481) training like healthy adults. Nevertheless, these individuals require careful individual monitoring and periodic muscle function tests (479).

### Multiple Sclerosis

Most concerns regarding exercise safety in multiple sclerosis patients center around potential adverse effects from the autonomic dysfunction that frequently accompanies the disease and exacerbations of the disease via exercise-induced thermal stress. Although relatively little research examines these questions, a recent review article (482) concluded that endurance and resistance exercise training beneficially affect moderately impaired multiple sclerosis patients. Encouraging evidence from individual research articles supports these conclusions: individuals with multiple sclerosis can perform endurance exercise at intensities above the anaerobic threshold without developing significant neurologic symptoms (483), experience training-induced cardiovascular adaptations (484), and gain significant strength via resistance training (485). Until more research clarifies how people with multiple sclerosis respond to exercise, these patients (especially in those suffering more than moderate impairments) deserve a conservative exercise prescription.

### Cancer

The medical community increasingly accepts exercise as an important component of rehabilitation for cancer patients. Besides counteracting the effects of inactivity and improving psychological status (486), evidence suggests moderate exercise improves immune function (188–192). Although general guidelines for aerobic exercise training generally meet their demands (487), cancer patients should typically exercise at lower intensities. Patients with bone malignancies (particularly of the spine, pelvis, femur, and ribs) require non-weight-bearing modalities. Individuals suffering associated conditions that increase the risk of bruising, fractures, or falls should perform resistance exercise on machines rather than with free weights to minimize the risk of injury.

Besides the disease itself, the treatments for cancer challenge exercise capacity and prescription. Cancer treatments can induce cytotoxicity, immunosuppression, bleeding disorders, and anemia. Further, direct or peripheral effects of cancer or its treatments inhibit exercise performance by causing (a) direct damage to cardiac and pulmonary tissue, (b) difficulty in maintaining adequate nutrition, hydration, and electrolyte balance, and (c) fatigue and infection.

### Considerations in Selected Groups within the Able-Bodied Population

Pregnant women, children, and the elderly possess unique physical, physiological, and behavioral characteristics that merit consideration in the design of exercise programs.

**TABLE 61.12** Contraindications for Exercising During Pregnancy

Relative contraindications
Severe anemia
Unevaluated maternal cardiac arrhythmia
Chronic bronchitis
Poorly controlled type I diabetes
Extreme morbid obesity
Extreme underweight
History of extremely sedentary lifestyle
Intrauterine growth restriction in current pregnancy
Poorly controlled hypertension
Orthopedic limitations
Poorly controlled seizure disorder
Poorly controlled hyperthyroidism
Heavy smoker
Absolute contraindications
Hemodynamically significant heart disease
Restrictive lung disease
Incompetent cervix/cerclage
Multiple gestation at risk for premature labor
Persistent second- or third-trimester bleeding
Placenta previa after 26 wk of gestation
Premature labor during the current pregnancy
Ruptured membranes
Preeclampsia/pregnancy-induced hypertension

From American College of Obstetricians and Gynecologists. Exercise during pregnancy and the postpartum period. ACOG Committee Opinion No. 267. *Obstet Gynecol.* 2002;99:171–173.

### Pregnancy

Previous concerns about exercise during pregnancy related to the competition between mother and fetus for oxygen and substrates, thermoregulatory issues, and uterine contractions. Currently, however, no evidence indicates that healthy pregnant women should limit exercise intensity for fear of adverse effects (99).

The American College of Obstetricians and Gynecologists has established contraindications for exercise during pregnancy (Table 61-12) and exercise recommendations for women without risk factors for adverse maternal or perinatal outcomes (Table 61-13). Equipped with an understanding of the signs and symptoms for discontinuing exercise (Table 61-14), pregnant women can safely exercise during pregnancy within these recommendations. Women who exercised regularly prior to becoming pregnant can continue their training with appropriate modifications; previously sedentary women or those managing medical complications should obtain physician approval before initiating a new exercise program during pregnancy (488).

### Children and Adolescents

Decreasing levels of physical activity have contributed to the recent rise in childhood and adolescent obesity in the United States. To reverse this trend in inactivity, children and adolescents must experience positive physical activity/exercise opportunities. In developing physical activity programs for this group,

**TABLE 61.13** Recommendations for Exercise in Pregnancy and Postpartum

1. During pregnancy, women can continue to exercise and derive health benefits from mild-to-moderate exercise routines. Regular exercise (at least three times per week) is preferable to intermittent activity.
2. Women should avoid exercise in the supine position after the first trimester. Such a position is associated with decreased cardiac output in most pregnant women. Because the remaining cardiac output will be preferentially distributed away from splanchnic beds (including the uterus) during vigorous exercise, such regimens are best avoided during pregnancy. Prolonged periods of motionless standing should also be avoided.
3. Women should be aware of the decreased oxygen available for aerobic exercise during pregnancy. They should be encouraged to modify the intensity of their exercise according to maternal symptoms. Pregnant women should stop exercising when fatigued and not exercise to exhaustion. Weight-bearing exercises may under some circumstances be continued at intensities similar to those prior to pregnancy throughout pregnancy. Non-weight-bearing exercises, such as cycling or swimming, will minimize the risk of injury and facilitate the continuation of exercise during pregnancy.
4. Morphologic changes in pregnancy should serve as a relative contraindication to types of exercise in which loss of balance could be detrimental to maternal or fetal well-being, especially in the third trimester. Further, any type of exercise involving the potential for even mild abdominal trauma should be avoided.
5. Pregnancy requires an additional 300 kcal/d in order to maintain metabolic homeostasis. Thus, women who exercise during pregnancy should be particularly careful to ensure an adequate diet.
6. Pregnant women who exercise in the first trimester should augment heat dissipation by ensuring adequate hydration, appropriate clothing, and optimal environmental surroundings during exercise.
7. Many of the physiologic and morphologic changes of pregnancy persist 4 to 6 wk postpartum. Thus, prepregnancy exercise routines should be resumed gradually, based on a woman's physical capability.

From American College of Obstetricians and Gynecologists. *Exercise During Pregnancy and the Postpartum Period* (Technical Bulletin 28-189). Washington, DC: ACOG; 1994.

consider their maturity, skill levels, medical conditions, and prior physical activity. Some general guidelines include (a) providing a variety of activities that exercise all major large muscles; (b) focusing on active, creative, enjoyable play in very young children; (c) encouraging children 5 to 12 years old to accumulate a minimum of 60 minutes of age-appropriate moderate or vigorous, intermittent activity on most or all days of the week; (d) encouraging older children to participate in an additional 20 to 30 minutes of higher-intensity activity at least three times per week; and (e) gradually progressing exercise volume (99). In addition to immediate health benefits, positive exercise experiences during youth translate into increased adulthood activity.

Safety represents a primary concern in designing exercise programs for children, as they are anatomically, physiologically,

**TABLE 61.14** Reasons for Pregnant Women to Discontinue Exercise and Consult a Physician

1. Any signs of bloody discharge from the vagina
2. Any “gush” of fluid from the vagina (premature rupture of membranes)
3. Persistent contractions (>6 to 8/h) that may suggest onset of premature labor
4. Unexplained abdominal pain
5. Absence of or decreased fetal movement
6. Sudden swelling of the ankles, hands, and face
7. Persistent, severe headaches and/or visual disturbance
8. Unexplained spells of faintness or dizziness
9. Swelling, pain, and redness in the calf of one leg (phlebitis)
10. Elevation of pulse rate or blood pressure that persists after exercise
11. Excessive fatigue, palpitations, chest pain
12. Insufficient weight gain (<1.0 kg/mo during last two trimesters)
13. Dyspnea prior to exertion
14. Muscle weakness

From Wolfe LA, Hall P, Webb KA, et al. Prescription of aerobic exercise during pregnancy. *Sports Med.* 1989;8:273–301 and American College of Obstetricians and Gynecologists. Exercise during pregnancy and the postpartum period. ACOG Committee Opinion No. 267. *Obstet Gynecol.* 2002;99:171–173.

and psychologically immature (99). This immaturity magnifies the risk of injury for any activity because the child’s body already combats the stress of growth and development. Additional concerns include an increased head-to-body size ratio, vulnerability of growing connective tissue, and underdeveloped motor skills (489). Using appropriate equipment, matching competition to maturation or skill, providing adequate skill preparation, and liberalizing rules all reduce the possibility of injury.

Additionally, children possess a less robust thermoregulatory capacity than adults: children begin sweating at a higher core temperature, sweat less at a given temperature, and acclimatize more slowly to the heat (490). An increased ratio of surface area to body mass also alters a child’s interaction with his or her environment. Limiting strenuous prolonged exercise in extreme environmental conditions, promoting good hydration practices, and encouraging appropriate clothing minimize the potential for thermoregulatory issues (99).

Like adults, children respond to resistance training by significantly increasing strength (99,229). Unlike adults, most strength gains result from neural development rather than frank muscle hypertrophy. Safe resistance training programs for children include close adult supervision, avoidance of maximal resistance loads, strong emphasis on proper lifting technique, and low-resistance high-volume workouts (99).

### Elderly

Although basic exercise prescription models generally suffice for older adults, the elderly typically present with disease processes, orthopedic issues, and/or unique goals that

require manipulations to the exercise program. By definition, the ACSM considers older adults at least of moderate risk, so even otherwise healthy elderly individuals should obtain medical clearance before starting an exercise program (see Table 61-9).

To limit the physiological stress of physical activity in new exercisers, older adults can divide their aerobic exercise sessions into short bouts; low impact modes (walking, cycling, and swimming) also minimize joint stress. In assigning exercise intensities, the variability in maximal heart rate in individuals greater than 65 years old suggests direct measurements of peak heart rate produce more valid and reliable prescriptions than age-predicted estimations of maximal heart rate (99).

Resistance training can considerably benefit the elderly (491). Given the role of muscular strength and endurance in activities of daily life (e.g., gripping objects), maintaining independence, and reducing the risk of falls, resistance training deserves special effort and attention for older adults. Although typical guidelines for resistance training apply to the elderly, older adults require uninterrupted supervision during the initiation of a resistance training program (99). The elderly also require exercises to maintain a functional range of motion. Improved flexibility likely decreases the risk of musculoskeletal injury and assists in the prevention of falls by improving balance and agility. Standard guidelines for improving flexibility apply to older adults (99).

# Aquatic Rehabilitation

## INTRODUCTION AND BRIEF HISTORY

### Historical Applications

Throughout all recorded history, the sick and suffering have resorted to springs, baths, and pools for their soothing, healing, and powerful effects. “Taking the waters,” soaking in baths and pools, and resting at places called spas played an important social and spiritual role in the river valley civilizations of Mesopotamia, Egypt, India, and China. Ritual bathing pools were widely used for individual and social renewal and healing. Healing water rituals also appeared in ancient Greek, Hebrew, Roman, Christian, and Islamic cultures (1). During the Middle Ages in Europe, the beginnings of formal resorts formed for the purposes of healing began to emerge. These became the progenitors of the current group of European spas. Dr. Sidney Licht (2) a physiatrist and founding member of the American Society of Medical Hydrology and Climatology (ASMH), defined a spa as a “place where mineral containing waters flow from the ground naturally, or to which it is pumped or conducted, and is there used for therapeutic purposes.”

In the decades before the American Civil War, major health reforms swept the nation, and numerous hydropathic establishments, institutes, and medical colleges were built for the practice of water cure cold water bathing. The American Medical Association Committee on Sanitaria and Springs published its first national report on sanatoria in 1880. At the turn of the century, medical men such as Simon Baruch, John Harvey Kellogg, and Guy Hinsdale regularly conducted clinical hydrotherapeutic experiments and prescribed aquatic therapeutics. Baruch established the American medical standards for hydrotherapy in *The Principles and Practice of Hydrotherapy*, and in 1921, shortly before he died, Baruch published his last book, *An Epitome of Hydrotherapy* (3,4). Baruch writes in the Preface to the 2nd edition of *The Principles and Practice of Hydrotherapy*, “So flexible is this therapeutic agent that, unlike medicinal remedies, it may be utilized to meet indications which seem contradictory to the uninitiated” (3). This statement holds true today.

Although most writings concerned the internal and external curative benefits of the waters, baths, and pools, limited emphasis was placed on water exercise. In 1911, Charles Leroy Lowman began using therapeutic tubs to treat spastic patients and those with cerebral palsy. Lowman founded the Orthopaedic Hospital in Los Angeles in 1913, later to become Rancho Los Amigos. He visited the Spaulding School for Crippled Children in Chicago, where he observed paralyzed

patients exercising in a wooden tank. On his return to California, he transformed the hospital’s lily pond into two therapeutic pools (3,4). He also made a motion picture showing the various types of cases treated with pool therapy. At Warm Springs, Georgia, Leroy Hubbard developed his famous tank, and in 1924, Warm Springs received its most famous aquatic patient, Franklin D. Roosevelt.

At Saratoga Springs, New York, financier Bernard M. Baruch, Roosevelt’s friend and the son of Dr. Simon Baruch, headed a special commission to plan a scientific American spa (5). The commission studied spa design, natural treatments, and efficient operations based on what was then felt to be the sound medical and scientific care for chronically ill patients, especially those suffering from cardiac, vascular, and circulatory ailments, and selected Dr. Walter S. McClellan to be the Medical Spa Director (6). Drs. W. E. Fitch and McClellan, and several other spa doctors, scientific directors, and spa general managers met at French Lick Spa to organize “an association which would be of mutual benefit to everyone interested in the advancement of (Medical) Hydrology in this country” (7). A wealth of information, research, and articles on health resort medicine, spa therapy, and pool treatments appeared in professional journals during the 1930s. At Northwestern University Medical School in Chicago, Dr. John S. Coulter (8) presented lectures on physical therapy that he placed within the history of spa medicine. In 1933, the Simon Baruch Research Institute of Balneology at Saratoga Springs Spa was established, and the facility began the printing of their scientific bulletin, *The Publications of Saratoga Spa*. At Hot Springs, Arkansas, a warm swimming pool was installed for special underwater physical therapy exercises and pool therapy treatments for chronic arthritic patients (9). By 1937, Dr. Charles Leroy Lowman published his *Technique of Underwater Gymnastics: A Study in Practical Application*, in which he detailed pool therapy methods of specific underwater exercises that “carefully regulated dosage, character, frequency, and duration for remedying bodily deformities and restoring muscle function” (10). During the 1950s, the National Foundation for Infantile Paralysis supported the corrective swimming pools and hydrogymnastics of Charles L. Lowman and the therapeutic use of pools and tanks for the treatment of poliomyelitis. In 1962, Drs. Sidney Licht, Herman Flax, Sigmund Foster, William Erdman, Lucille Eising, J. Wayne McFarland, Jens Henriksen, and Richard Gubner organized the ASMH, which traditionally continues to meet at the annual meeting of the American Academy of Physical Medicine and Rehabilitation.

### Current Trends and Uses

With the end of the polio epidemic and the rise of newer and more exciting technology in rehabilitative therapeutics, the use of the aquatic environment in rehabilitation waned. Medical hydrology became a smaller and smaller component of physiatric and physical therapy training. Principles of medical hydrology and aquatic rehabilitation that were formerly an important part of a therapist's training program were deemphasized. Since the mid-1980s, the increase in health-care costs, constraints on physical therapy utilization under managed care, and an emerging public understanding of the value of aquatic rehabilitation and better training within the rehabilitative professions have begun to drive a broader utilization of aquatic therapies. Fortunately, basic science research in the biologic effects of immersion accelerated during the late 1960s for two fortuitous reasons. Water was recognized as a wonderful surrogate for the weightlessness of space, and as we prepared to place humans outside gravity, it became essential to forecast the effects of space flight. At the same time, Murray Epstein and other endocrinologists realized that aquatic immersion was a benign means of simulating central volume expansion to better understand volume homeostasis. The end result of these research efforts has been that aquatic therapy has a considerable foundation of high-quality basic science research.

## THE PHYSICS OF WATER AND ITS RELATIONSHIP TO AQUATIC REHABILITATION

### Density and Specific Gravity

Density is defined as mass per unit volume and is given the Greek letter rho ( $\rho$ ). The relationship of  $\rho$  to mass and volume is characterized by the following formula:

$$\rho = m/V$$

where  $m$  is the mass of a substance whose volume is  $V$ . Density is measured in the international system by  $\text{kg/m}^3$  and occasionally as  $\text{g/cm}^3$ . Density is a temperature-dependent variable, although much less so for solids and liquids than for gases. In addition to density, substances are defined by their specific gravity, the ratio of the density of that substance to the density of water. By definition, water has a specific gravity equal to 1.00 at  $4^\circ\text{C}$ . Salt water density varies considerably, from ocean to ocean, up to the Dead Sea, with a density greater than 1.16 (11). (The Black Sea has the lowest ocean density nearly approximating 1, due to significant fresh water inflow, but this has created significant environmental concerns.) Although the human body is mostly water, the body's density is slightly less than water and averages a specific gravity of 0.974, with males averaging higher density than females. Lean body mass, which includes bone, muscle, connective tissue, and organs, has a typical density near 1.10, whereas fat mass, which includes both essential body fat plus fat in excess of essential needs, has a density of about 0.90 (12). Consequently, the human body

displaces a volume of water weighing slightly more than the body, forcing the body upward by a force equal to the volume of the water displaced. The buoyancy differences between lean and fat body mass make aquatic activity particularly useful for severely obese individuals, for whom land-based exercise may produce joint pain.

### Hydrostatic Pressure

Pressure is defined as force per unit area, where the force  $F$  by convention is understood to act perpendicularly to the surface area  $A$ . This relationship is

$$P = F/A$$

The standard international unit of pressure is called a pascal (Pa), after the French scientist Blaise Pascal, and is measured in Newtons (N)/ $\text{m}^2$ , dynes/ $\text{cm}^2$ ,  $\text{kg/m}^2$ , and pounds per square inch (PSI). Fluids have been experimentally found to exert pressure in all directions. The pressure exerted on a theoretical point surrounded by a fluid is equal from all directions. Obviously, if unequal pressure were being exerted, the point would move until the pressures were equalized on it. Pressure is directly proportional to both the liquid density and the immersion depth, when the fluid is incompressible, as water is at the depths used in therapeutic environments. Because pressure responds not only to the fluid depth but also to any force exerted on its surface, the pressure of the Earth's atmosphere is an important contributor to the total force from immersion. Water exerts a pressure of 22.4 mmHg for every foot of water depth, which translates to 0.73 mmHg/cm or slightly under 2 mmHg/in. of  $\text{H}_2\text{O}$  depth. Thus, a body immersed to a depth of 48 in. is subjected to a distal pressure equal to 88.9 mmHg, far greater than venous or lymphatic pressures. This external compressive force significantly aids the resolution of edema in an injured body part or where postsurgical edema resolution is a therapeutic goal.

### Buoyancy

Buoyancy causes immersed objects to have less apparent weight than the same object on land. Buoyancy, a force opposite to gravity, acts on the object with a force generated by the volume of  $\text{H}_2\text{O}$  displaced. This principle was discovered by Archimedes (287 to 212 B.C.) and is the reason that water can be used to advantage in the management of medical problems, such as arthritis or severe obesity requiring weight off-loading. A human with a specific gravity of 0.97 will reach floating equilibrium when 97% of his or her volume is submerged.

Because the force of buoyancy is an upward force, there are important consequences in the therapeutic aquatic environment. The center of gravity is a point at which all force moments are in equilibrium. For an average male adult human being standing in the "anatomic" position, this point is located slightly posterior to the midsagittal plane and at about the level of the second sacral vertebra, because the human body is nonuniform with respect to density and varies depending upon body build within a radius of 1.9 to 9 cm (13). The lungs

obviously are less dense than the lower limbs, for example. The center of buoyancy is defined as the center of all buoyancy force moments summing on each body segment. Typically, the human center of buoyancy is in the midchest. The difference between the center of gravity (a downward force) and the center of buoyancy (an upward force) may generate rotational torque. This rotational torque may produce instability for some patients and should be carefully monitored, preferably by a therapist in the pool with the patient.

## Water in Motion

### Flow Characteristics

When water moves smoothly, in layers moving at the same speed, the water is defined as in laminar or streamline flow. When water moves more rapidly, even minor oscillations create uneven flow, and parallel paths are knocked out of alignment, resulting in turbulent flow. Within the mass of water, flow patterns arise that run dramatically out of parallel. These paths are called eddy currents. An example of the latter are the eddy currents that form in the blood stream behind artery walls encrusted with cholesterol plaque. Turbulent flow absorbs energy at a much greater rate than streamline flow, and the internal friction within the fluid determines the rate of energy absorption. This internal friction is called viscosity. The major determinants of water motion are viscosity, turbulence, and speed. Flow rates decrease when turbulence occurs, largely due to the significant nonlinear increase in internal friction in the fluid. The onset of turbulent flow obviously is a function of fluid velocity, but it is also related to fluid density, viscosity, and enclosure radius. The transition from laminar flow to turbulent flow often occurs abruptly with increasing velocity.

### Viscosity and Drag

Viscosity refers to the magnitude of internal friction specific to the fluid. As layers of fluid molecules are set into motion, molecular attraction creates resistance to movement and is detected as friction. Energy must be exerted to create movement, and as in the first law of thermodynamics, energy is never lost but rather is transformed and stored as potential or kinetic energy. Some energy is transformed into heat, some into kinetic energy, and some may be stored as potential energy by increasing surface tension. Fluids are in part defined by individual viscosity, expressed quantitatively as the coefficient of viscosity (Table 62-1). The greater the coefficient, the more viscous the fluid and the greater the force required to create movement within the fluid. This force is proportionate to the number of molecules of fluid set into motion and the velocity of movement. The SI unit of measurement of viscosity is called a poise, after the French scientist J. L. Poiseuille (1799 to 1869), who studied the physics of blood circulation. Because velocity is described by distance/time, viscosity is the first time-dependent property. An equation that expresses this relationship must define the volume of the fluid in motion, measured as the area ( $A$ ), depth ( $l$ ), and velocity ( $v$ ) of the motion.

$$F = \eta A \frac{v}{l}$$

**TABLE 62.1** Coefficients of Viscosities for a Variety of Fluids

Fluid	Temperature (°C)	Coefficient of Viscosity $\eta$ (Pa·s)
Water	0	$1.8 \times 10^{-3}$
Whole blood	37	$4 \times 10^{-3}$
Blood plasma	37	$1.5 \times 10^{-3}$
Engine oil (SAE 10)	30	$200 \times 10^{-3}$
Glycerin	20	$1,500 \times 10^{-3}$
Water vapor	100	$0.013 \times 10^{-3}$

Water is intermediate in viscosity as liquids go, but it still presents much resistance to movement. Calculation of these forces has been done and a mathematical model has been developed using a prosthetic leg model (14). Under turbulent flow conditions, this resistance increases as a log function of velocity. The greatest surface area drag on a swimming man is his head, although the negative pressure following the swimmer causes the greatest force resisting forward movement. There is turbulence produced by fast-moving body surface areas and a drag force produced by the turbulence behind. Viscosity, with all its attendant physical properties, is a quality that makes water a useful strengthening medium. Viscous resistance increases as more force is exerted against it, but resistance drops to zero almost immediately on cessation of force because there is only a small amount of inertia (viscosity effectively counteracts inertial momentum). Thus, when a rehabilitating person feels pain and stops movement, the force decreases precipitously, and water viscosity damps movement almost instantaneously. This allows great control of strengthening activities within the envelope of patient movement comfort.

### Specific Heat

Water is used therapeutically in all three of its thermal states: solid, liquid, and gas. A major reason for its usefulness lies in the physics of aquatic thermodynamics. All substances on earth possess energy stored as heat. This energy is measured in a quantity called a calorie (cal). A calorie is defined as the heat required to raise the temperature of 1 g of water by 1°C (e.g., from 14.5°C to 15.5°C). The energy required to raise temperature is defined in kilocalories, the amount of energy required to raise 1 kg of water 1°C, and this unit by convention is termed a Calorie (with a capital C) (Cal). This is the unit in which food energy content is measured. The British system measures heat energy in British Thermal Units (BTU), the amount of energy required to raise 1 lb of water 1°F (1 BTU = 0.252 Cal). A mass of water possesses a measurable amount of stored energy in the form of heat. Energy stored may be released through a change to a lower temperature, or additional energy may raise the water temperature. The formula defining the quantity of energy required or released is

$$Q = mc\Delta T^{\circ}$$

where  $m$  equals the mass of water,  $c$  equals the specific heat capacity of the fluid, and  $\Delta T^\circ$  equals the change in temperature. The work required to produce this energy is called the mechanical equivalent of heat and is measured in joules (J). One Calorie is equivalent to  $4.18 \times 10^3$  J. A body immersed in a mass of water becomes a dynamic system. If the temperature of the water exceeds the temperature of the submerged body, the system equilibrates to a different level, with the submerged body warming through transference of heat energy from the water, and the water cooling through loss of heat energy to the body. By the first law of thermodynamics, the total heat (and thus energy) content of the system remains the same. Energy applied to this system increases the kinetic energy of some of the molecules, and when high kinetic energy molecules collide with lower kinetic energy molecules, they transfer some of their energy, increasing and equilibrating the total energy of the system. Water is defined as having a specific heat capacity equal to 1.00. Air, in contrast, has a far lower specific heat capacity = 0.001. Thus, water retains heat 1,000 times more than an equal volume of air.

### Thermal Energy Transfer

The therapeutic utility of water is greatly dependent on both its ability to retain heat and its ability to transfer heat energy. Exchange of energy in the form of heat occurs in three ways: conduction, convection, and radiation. Conduction may be thought of as occurring through molecular collisions that take place over a small distance. For example, a hydrocollator pack transfers heat by conduction. Substances vary widely in their ability to conduct heat. Convection requires the mass movement of large numbers of molecules over a large distance (i.e., fluid flow). For example, a whirlpool bath transfers heat by convection. Heat transfer across a gradient is measured by the amount of heat in calories transferred per second across an imaginary membrane. Liquids and gases are generally poor conductors but good convectors. Water is an efficient conductor of heat and transfers heat 25 times faster than air. Radiation transfers heat through the transmission of electromagnetic waves. For example, a heating lamp transfers heat by radiation. The rate of radiant energy transfer from a body is proportional to the fourth power of its temperature in degrees Kelvin. It is also proportional to surface area, to the emissivity of the material, and to the second power of the distance between the energy-radiating and energy-absorbing bodies. The thermal conductive property of water, in combination with water's high specific heat, makes its use in rehabilitation versatile, as it retains heat or cold while transferring it easily to the immersed body part.

## BIOLOGIC ASPECTS OF AQUATIC REHABILITATION

### Circulatory System Effects

Water begins to exert external pressure on the body immediately on immersion. Intrinsic pressure within the venous and lymphatic side of the circulation is much lower than pressure on the arterial side of the system. Venous and lymphatic

pressures vary, depending on the part of the body and its vertical relationship to the heart, but are in part controlled by the system of valves within both systems, which prevents backflow. These one-way valves act to divide the large vertical column fluid into many short columns with little vertical height. This allows much lower hydrostatic pressure gradients inside the vessel wall, so that the maximum venous pressure is 30 mm Hg peripherally, decreasing steadily as blood travels toward the right atrium, which has a negative pressure of  $-2$  to  $-4$  mm Hg. The role of these valves in maintaining a low-pressure system is critical, as can be observed when they fail, creating venous varicosities due to the lack of sufficient vessel wall strength to support the increased height of the fluid column. Consequently, venous and lymphatic returns are sensitive to external pressure changes, including compression from surrounding muscles and from external water pressure. During water immersion, hydrostatic pressure displaces blood upward through this one-way system, first into the thighs, then into the abdominal cavity vessels, and finally into the great vessels of the chest cavity and into the heart. Central venous pressure begins to increase with immersion to the xiphoid and increases until the body is completely immersed. Right atrial distension occurs, and pressure increases by 14 to 18 mm Hg during immersion to the neck, going from about  $-2$  to  $-4$  mm Hg to  $+14$  to  $+17$  mm Hg (15,16). The transmural pressure gradient of the right atrium increases significantly, measured by Arborelius and others at 13 mm Hg, going from 2 to 15 mm Hg. Extra systoles may result, especially early into immersion (15).

Pulmonary blood flow increases with increased central blood volume and pressure. Mean pulmonary artery wedge pressure increases from 5 mm Hg on land to 22 mm Hg during immersion to the neck (16). Most of the increased pulmonary blood volume is distributed in the larger vessels of the pulmonary vascular bed and only a small percentage (5% or less) at the capillary level. This is validated by the fact that the diffusion capacity of the lungs changes very little.

Central blood volume increased by 0.7 L in Arborelius' classic study (15). This represents a 60% increase in central volume, with one third of this volume taken up by the heart and the remainder by the great vessels of the lungs. Cardiac volume increases 27% to 30% with immersion to the neck (17), but the heart is not a static receptacle. The healthy cardiac response to increased volume (stretch) is to increase the force of contraction. As the myocardium stretches, an improved actin/myosin filament relationship is produced, enhancing the myocardial efficiency (Starling's law) (18). Mean stroke volume increases 35% on average with immersion to the neck from a resting baseline of about 71 mL/beat to about 100 mL/beat, which is close to the exercise maximum for a sedentary, deconditioned individual on land (19,20). There is both an increase in end-diastolic volume and a decrease in end-systolic volume (15). Stroke volume is one of the major determinants of the increase in cardiac output seen with training because heart rate response ranges remain relatively fixed (19).

Most of the changes are temperature dependent, with cardiac output increasing progressively with increasing water

temperatures. Weston found cardiac output to increase by 30% at 33°C rising to 121% at 39°C (17). There is considerable individual variance in the many studies assessing this phenomenon.

As cardiac filling and stroke volume increase with deeper immersion from symphysis to xiphoid, the heart rate typically decreases (16,21). This decrease is variable, with the amount of decrease dependent on water temperature. Typically, at average pool temperatures, the rate decreases by 12% to 15% (17). There is a significant relationship between water temperature and heart rate. At 25°C, the heart rate decreases by approximately 12 to 15 beats/minute (17,22), whereas at thermoneutral temperatures, the rate of decrease is less than 15%, and in warm water, the rate generally increases significantly, contributing to the major increase in cardiac output at high temperatures. The reduction variability is believed to be related to decreased peripheral resistance at higher temperatures and increased vagal effects (23). Ongoing work in our lab, has corroborated the heart rate effects, with healthy college-aged students showing a reduction of heart rate in cool (30°C) water, an increase to about baseline in neutral (36°C), and elevation averaging about 10% in warm water (39°C). (Becker BE, Hildenbrand K, Sanders JP, et al. Biophysiologic Effects of Warm Water Immersion. *International Journal of Aquatic Research & Education*. 2009;3(1):24–37.) At the same time, by monitoring autonomic nervous system activity, we found elevation of sympathetic activity in cool water, substantially reducing in warm water, with vagal power increasing through the cool to warm immersion sequence. (Becker BE, Hildenbrand K, Sanders JP, et al. Age-Dependent Autonomic Changes Following Immersion in Cool, Neutral, and Warm Water Temperatures. *International Journal of Aquatic Research and Education*. 2010;4(2):127–146.)

The most efficient way for the heart to deliver more blood during exercise is to increase stroke volume. Maximal myocardial oxygen consumption efficiency (peak heart muscle efficiency) occurs when stroke volume increases because heart rate acceleration is a less efficient means of increasing output (18,24). Thus, as cardiovascular conditioning occurs, cardiac output increases are achieved through smaller increases in heart rate but greater stroke volumes per beat. This is the reason that conditioned athletes are able to maintain lower pulse rates for a given cardiac output than those who are deconditioned (18,24).

Several studies have validated the use of aquatic environments in cardiovascular rehabilitation after infarct and ischemic cardiomyopathy by actively rehabilitating heart patients in an aquatic environment (25). Tei and Tanaka found that a single brief immersion in a hot water (41°C) bath decreased both pulmonary wedge pressure and right atrial pressure by nearly 30%. Over a period of 1 month of daily therapy, patients showed nearly a 30% increase in ejection fraction, significantly improving by one and sometimes two New York Heart Association classifications (26–30). Recent work on the use of aquatic exercise in heart disease has shown significant benefit in both mild to moderate heart failure and in general cardiac rehab (31–33). Severe congestive heart failure may still be a contraindication to aquatic exercise, however (34).

Because the ultimate purpose of the heart as an organ is to pump blood, its ultimate measure of performance is the amount of blood pumped per unit time. Cardiac output is the product of stroke volume times pulse rate per unit time. Submersion to the neck increases cardiac output by more than 30% (15). Output increases by about 1,500 mL/minute, of which 50% is directed to increased muscle blood flow (15). Normal resting cardiac output is approximately 5 L/minute. Maximum output in a conditioned athlete is about 40 L/minute, which is equivalent to 205 mL/beat times 195 beats/minute. Maximum output at exercise for a sedentary individual on land is approximately 20 L/minute, equivalent to 105 mL/beat times 195 beats/minute (24). Because immersion to the neck produces a cardiac stroke volume of about 100 mL/beat, a resting pulse of 86 beats/minute produces a cardiac output of 8.6 L/minute and is already producing increased cardiac work. The increase in cardiac output appears to be somewhat age dependent, with younger subjects demonstrating greater increases (59%) than older subjects (22%) (35). The increase is also highly temperature dependent, varying directly with temperature increase from 30% at 33°C to 121% at 39°C (17). Recent research has shown that conditioned athletes demonstrate an even greater increase in cardiac output than untrained control subjects during immersed exercise and that this increase was sustained for longer periods than in the control group (36). Therefore, the myth that water exercise is not aerobically efficient is faulty; it may be an ideal cardiovascular conditioning medium. There is an emerging body of research on water exercise–induced cardiac output, but significant work needs to be done to delineate the effects of age, gender, temperature, and conditioning, as well as to explain the significant individual response variations. The cascade of cardiovascular responses to immersion is shown in Figure 62-1.

During immersion to the neck, systemic vascular resistance decreases by 30% (15). Diminished sympathetic vasoconstriction produces this decrease, with peripheral venous tone decreasing by 30% from 17 to 12 mm Hg at thermoneutral temperatures (37). Total peripheral resistance decreases during the first hour of immersion and remains low for several hours thereafter. This decrease is related to temperature, with higher temperatures producing greater reductions. This resistance drop decreases end-diastolic pressures. Immersed systolic pressures increase with increasing workload, as they do on land, but these increases appear to be reduced in magnitude when compared with equivalent land-based work (38). Venous pressures also decrease during immersion because less vascular tone is required to support the system.

The effect of immersion on blood pressure has been quite extensively studied. A consistent finding has been the striking individual variation, but trends have emerged that are useful. Very short-term immersion (10 minutes) in thermoneutral temperatures has been found to slightly increase both systolic and diastolic pressures, perhaps as part of the thermal accommodation process (38). By contrast, a pilot study in our institution found that mean arterial pressures demonstrated a 15% to 25% decrease at 5 minutes of immersion. Other studies conducted in carefully controlled environments have found no

**FIGURE 62-1.** Cardiovascular schematic.

effects or actual decreases in pressures during longer immersion periods more typical of therapeutic sessions (39). In an important study for aquatic rehabilitation, Coruzzi et al. (40) found that longer immersion produced significant decreases in mean arterial pressure, with sodium-sensitive hypertensive patients showing even greater decreases (18 to 20 mm Hg) than normotensive patients, and sodium-insensitive patients showing smaller decreases (5 to 14 mm Hg). No studies have demonstrated consistent sustained increases in systolic pressure with prolonged immersion, although several have found no significant decrease. Based on a substantial body of research, the therapeutic pool appears to be both a safe and potentially therapeutic environment for both normotensive and hypertensive patients, with both sodium-sensitive and sodium-insensitive hypertensive individuals demonstrating decreases in pressure during therapeutically customary periods of immersion (41).

In 1989, Gleim and Nicholas (38) found that oxygen consumption ( $\text{VO}_2$ ) was three times greater at a given running speed (53 m/minute) in water than on land. Therefore, during water walking and running, only one-half to one-third the speed was required to achieve the same metabolic intensity

as on land (38). It is important to note that the relationship of heart rate to  $\text{VO}_2$  parallels the relationship during land-based exercise, even with accounting for the heart rate decrease in water. Consequently, metabolic intensity in water may be predicted as on land from monitoring heart rate.

### Pulmonary System Effects

The pulmonary system is profoundly affected by immersion of the body to the level of the thorax. Part of the effect is due to the shift of blood into the chest cavity, and part is due to compression of the chest wall itself by water. The combined effect is to alter pulmonary function, increase the work of breathing, and change respiratory dynamics.

Functional residual capacity reduces to about 54% of the normal value with immersion to the xiphoid (42). Most of this loss is due to reduction in expiratory reserve volume (ERV), which decreases by 75% at this level of immersion (20). The change in this volume may be readily experienced at poolside: while sitting on the edge of the pool exhale normally, and then expel the rest of the reserve volume forcibly. Take a normal breath and then enter the water to neck level and perform the same

**FIGURE 62-2.** Effects of immersion on respiration.

experiment. The difference is very perceptible. Little air remains to exhale at the end point of relaxed exhalation. ERV is reduced to 11% of vital capacity, equal to breathing at a negative pressure of  $-20.5 \text{ cm H}_2\text{O}$  (42,43). There is some loss of residual volume, which decreases by 15% (42). Vital capacity decreases by about 6% to 9% when comparing neck submersion to controls submerged to the xiphoid (20,42). About 50% to 60% of this vital capacity reduction is due to increased thoracic blood volume, and 40% to 50% is due to hydrostatic forces counteracting the inspiratory musculature (20,42). Pressure on the rib cage shrinks the rib cage circumference by approximately 10% during submersion (18,20). The reduction in vital capacity does appear to fluctuate somewhat with temperature, with cooler water immersion ( $25^\circ\text{C}$ ) producing a greater reduction and warm water immersion ( $40^\circ\text{C}$ ) a smaller reduction (44). Figure 62-2 depicts the changes in pulmonary function during immersion.

The ability of the alveolar membrane to exchange gases is called diffusion capacity. Diffusion capacity of the lungs is reduced slightly, as is partial pressure of oxygen ( $\text{PO}_2$ ) as the lung beds become distended with blood shifted from the extremities and abdomen. Total intrapulmonary pressure shifts to the right by  $16 \text{ cm H}_2\text{O}$  (45). This causes airway resistance to the movement of air to increase by 58% or more, resulting from reduced lung volume (20). Expiratory flow rates are reduced, increasing the time to move air into and out of the lungs. Chest wall compliance is reduced as a result of the

pressure of water on the chest wall, increasing pleural pressure from a  $-1$  to  $+1 \text{ mm Hg}$  (15).

The combined effect of all these changes is to increase the total work of breathing. The total work of breathing for a tidal volume of 1 L increases by 60% during submersion to neck. Three quarters of this effort is attributable to an increase in elastic work (redistribution of blood from the thorax), and the rest is due to dynamic work (hydrostatic force on the thorax) (20,46). Thus, for an athlete accustomed to land-based conditioning exercises, a program of water-based exercise results in a significant workload challenge to the respiratory apparatus. In the authors' experience, this challenge can raise the efficiency of the respiratory system and improve athletic performance if the time spent in water conditioning is sufficient to achieve respiratory apparatus strength gains. A study in our lab completed in 2006 and pending publication at the time of this writing found that students completing a semester-long land-based aerobics class three times per week did not show an increase in respiratory endurance, although an aquatic aerobics group of students did show statistical improvement in inspiratory endurance, even though both groups showed equivalent improvement in  $\text{VO}_{2\text{max}}$  and increase in lean body mass (47). Corroboration of this experience has been found in two studies done on elite cyclists following an inspiratory muscle-strengthening program (48,49). These studies found athletic performance improvement as well as measurable strength and

endurance gains in respiratory function. A series of studies on patients with emphysema found that a treatment program involving breathing out into water for 30 minutes/day, 5 days/week for 8 weeks increased the  $\text{FeV}_{1\%}$ , percentage of forced vital capacity, and  $\text{PaO}_2$  and that clinical improvement followed these laboratory results (50–53). Inspiratory muscle strengthening has also been shown to improve both ventilatory function and perceived difficulty of breathing in tetraplegia (54). Aquatic exercise has been used successfully in both young and old asthmatic patients (33,55–57). (Becker B, Hildenbrand K, Freson T, et al. Development of an Aquatic Exercise Training Protocol for the Asthmatic Population. *International Journal of Aquatic Research and Education*. 2010;4(3):278–299.)

## Musculoskeletal Effects

### Joint Effects

As the body gradually immerses, water is displaced, creating a progressive off-loading of the immersed joints. With neck immersion, only about 15 lb of compressive force (the approximate weight of the head) is exerted on the spine, hips, and knees. A person immersed to the symphysis pubis has effectively off-loaded 40% of body weight, and when further immersed to the umbilicus, approximately 50%. Xiphoid immersion produces 60% or more off-loading, depending on whether the arms are overhead or beside the trunk (58). A body suspended or floating in water essentially counterbalances the downward effects of gravity by the upward force of buoyancy. This effect may be of great therapeutic utility. For example, a fractured pelvis may not become mechanically stable under full-body loading for a period of many weeks, but with water immersion, gravitational forces may be partially or completely offset so that only muscle torque forces are present on the fracture site(s), allowing “active-assisted” range-of-motion activities, gentle strength building, and even gait training.

The effects of buoyancy and water resistance make possible high levels of energy expenditure with relatively little movement and strain on lower-extremity joints. Off-loading occurs as a function of immersion but the water depth chosen may be adjusted for the amount of loading desired (see Fig. 62-1). The spine is especially well protected during aquatic exercise programs, thus facilitating early rehabilitation.

Shallow-water vertical exercises generally approximate closed-chain exercise, but with reduced joint loading because of the partial buoyancy counterforce. Deep-water exercises more generally approximate an open-chain system, as do horizontal exercises such as swimming. Paddles and other resistive equipment tend to close the kinetic chain. Thus, the therapist can vary the amount of open- versus closed-chain joint loading by varying the activity and resistive equipment used.

The ground counteracts the force exerted against the floor by the walking body. This force is termed *ground reaction force* and may easily be measured through a force plate. It has been found to differ substantially during walking in chest-deep water. Force plate tracings of the pressure generated during a gait cycle on dry land compared with chest-deep water walking are substantially reduced in magnitude by more than 50%

and are generated more slowly. Moreover, the forces are transmitted over a longer time interval during water walking (59). Clinically, this means that less joint compression is produced, and impact strain is diminished.

Water immersion causes significant effects on blood circulation through muscle tissue. These effects are caused by the compressive effects of immersion as well as by the reflex regulation of blood vessel tone. To resist blood pooling during dry conditions, sympathetic vasoconstriction tightens the resistance vessels of skeletal muscle. Immersion pressure removes the biological need for vasoconstriction, thus increasing muscle blood flow. During immersion, it is likely that most if not all of the increased cardiac output is redistributed to skin and muscle rather than to the splanchnic beds (37). Resting muscle blood flow has been found to more than double during immersion to the neck, and with this increased perfusion, muscle tissue washout was found to increase 130% above dry land clearance (60,61). Thus, oxygen delivery is significantly increased during immersion, as is the removal of muscle metabolic waste products. Hydrostatic forces add an additional circulatory drive to remove edema, muscle lactate, and other metabolic end products.

## Renal and Endocrine Effects

Because aquatic immersion produces central volume expansion in a pharmacologically and physiologically noninvasive manner, aquatic immersion serves as an excellent model for volume homeostasis. Aquatic immersion creates many effects on renal blood flow, on the renal regulatory systems, and on the endocrine systems. These effects have been studied extensively in both the American and international literatures. Epstein (37), one of the most skilled and prolific researchers in studying immersion effects on human, published an exhaustive summary of these effects in 1992. The flow of blood to the kidneys increases immediately on immersion. This causes an increase in creatinine clearance, a measure of renal efficiency, initially on immersion (37). Renal sympathetic nerve activity decreases because of the vagal response caused by left atrial distension, as discussed earlier in this chapter, and this decrease in sympathetic nerve activity increases renal tubular sodium transport (62). Calculated renal vascular resistance decreases by about one third (37). Renal venous pressure increases almost twofold (37). Sodium excretion increases tenfold in individuals with normal total-body sodium, and this sodium excretion is accompanied by free water, creating a major part of the diuretic effect of immersion. This increase in sodium excretion is a time-dependent phenomenon. Sodium excretion also increases as a function of depth, as a result of the shifting of circulating central blood volume (37). Potassium excretion also increases with immersion (39). The renal effects of immersion are shown in Figure 62-3.

Renal function is largely regulated by the hormones renin, aldosterone, and antidiuretic hormone (ADH); by the dopadopamine system; and by the atrial natriuretic peptide (ANP) system. All these hormones are greatly affected by immersion (Fig. 62-4). Aldosterone controls  $\text{Na}^+$  reabsorption in the distal renal tubule and accounts for most of the  $\text{Na}^+$  loss with immersion (37).

**FIGURE 62-3.** Renal function changes during immersion.

ADH release is significantly suppressed with immersion by 50% or more and is the other major contributor to diuresis. Another factor important in sodium regulation is ANP, which has both sodium excretion–facilitating and diuretic activity. ANP relaxes vascular smooth muscle and inhibits production of aldosterone. Immersion produces a prompt and continuing increase in ANP (39). Renal prostaglandin E secretion increases steadily through

the first 2 hours of immersion and then decreases gently over the next 3 hours. Plasma renin activity is reduced by 33% to 50% at 2 hours of immersion to the neck (37). Overall, immersion-induced central volume expansion causes an increase in urinary output accompanied by significant sodium and potassium excretion, beginning almost immediately on immersion and steadily increasing over several hours of immersion. This may

**FIGURE 62-4.** Renal hormone responses to immersion.

**FIGURE 62-5.** Catecholamine responses to immersion.

cause a decrease in blood pressure, and the resultant decrease may be sustained over a period of several hours. Immersion was historically one of the few effective ways of treating congestive heart failure noninvasively before the discovery of digitalis.

Accompanying the renal hormone effects are changes in the autonomic nervous system neurotransmitters, collectively called catecholamines, which act to regulate vascular resistance, cardiac rate, and force. The most important of these are epinephrine, norepinephrine, and dopamine. Catecholamine levels begin changing immediately on immersion (Fig. 62-5) (62,63).

## REHABILITATIVE APPLICATIONS

### Arthritis and Related Disorders

The value of the aquatic environment has a longer history in the management of arthritic diseases than in almost any other disease group. The losses that accompany chronic joint disease are many: loss of strength, loss of joint mobility and stability, and ultimately loss of functional capacity. It has been noted that rheumatoid patients as a group have lower than expected aerobic capacity and physical performance, with overall muscle strength 60% below that of age-matched control subjects. These deficits respond promptly to active rehabilitation, with well-tailored strengthening and endurance programs achieving gains in physical performance levels in as brief a time as 6 weeks (64). Long-term exercise regimens in rheumatoid patients over many years have been well tolerated, with resultant improvement in functional and other outcome measures (65). A well-researched Swedish study on the multidimensional value of dynamic ther-

apeutic exercise in rheumatoid arthritis was published in 1993 (66). A recent study of the cost-benefit in persons with osteoarthritis demonstrated that individuals enrolled in an Arthritis Foundation aquatics course significantly reduced perceived disability related to arthritis and improved perceived quality of life specific to physical health, although once the participation, transportation, and time costs of participation were calculated, the program did not show dramatic cost-effectiveness over standard care in reducing health-care expenses (67).

Because patients with arthritis have been shown to have decreased endurance, these individuals should participate in some form of aerobic exercise to enhance their overall fitness. Studies have demonstrated the benefits of aerobic exercise for many conditions, including fibromyalgia pain (33,68–74), rheumatoid arthritis (33,65,66,75–79) lupus (80), and osteoarthritis (33,64,81–85). Low-impact exercise has been shown to be more efficacious than medications in the self-management of osteoarthritis (86). Because the safest medium to reduce impact is the pool, the incorporation of aquatic exercise and/or swimming provides an advantageous alternative to manage arthritic symptoms. This argument has been substantiated in two studies of patient groups, with nonacute rheumatoid and osteoarthritis participating in water exercise regimens. In a study of rheumatoid patients, Danneskiold-Samsøe et al. found markedly increased isometric and isokinetic muscle strength of the quadriceps after only moderate training in the pool. Other gains included an increase in aerobic capacity, freedom of movement, and a higher degree of independence in activities of daily living (76). Postural sway, a factor associated with fall risk, has been shown to decrease in patients

undergoing a 6-week aquatic exercise intervention (64). Bunning et al. concluded that pool therapy was efficacious and achieved high compliance for those with osteoarthritis and that aquatic exercise should be the cornerstone of active rehabilitation for severe arthritis. Patients who participated in the study exhibited significant improvements in aerobic capacity and walk time and physical activity level and were less depressed than controls (82). More recent studies have corroborated these results (33,64,65,68,70,71,76–78,81,83,87).

The Arthritis Foundation, in conjunction with the YMCA, has developed a series of aquatic exercise regimens and classes for groups and individuals and certifies instructors. Training materials are available through the Arthritis Foundation (<http://www.arthritis.org/conditions/exercise/water-exercise.asp>). The original program was developed in 1983, was revised in 1989 and 1996, and includes range-of-motion, strengthening, and endurance-building exercises. Swimming skills are unnecessary. The certification process is sufficient so that the medical practitioner may feel comfortable referring a patient to the program. The authors' experience has been that patient adherence has been high, therapeutic value significant, and cost to the patient low. This has been corroborated elsewhere (64). The Arthritis Foundation has developed other programs, PACE (People with Arthritis Can Exercise), a community-based group program, and Joint Efforts, a gentle exercise program for sedentary older adults, and has also developed specific programs for juvenile arthritis and deep-water exercise.

### Spine Rehabilitation

Accurate diagnosis of patients' spinal injuries and observation of their initial responses to land-based or aquatic stabilization programs help determine further therapeutic exercise treatment. A transition from dry to wet exercise conditions minimizes certain dry land risks such as axial loading of the spine, falling onto a hard surface, and limits the chance of rapid uncontrolled motion from occurring. It also establishes a supportive training environment due to reduction in axial loads and better control of spinal and peripheral joint motion, seems to improve the psychological framework in which spine-pain patients function, provides a new therapeutic activity, decreases the risk of peripheral joint injury, and allows a return to prior activity. Moving from dry to wet environments also should be considered if patients cannot tolerate axial or gravitational loads, they require increased support in the presence of a strength or proprioceptive deficit (88), or they are at risk of a compression fracture due to decreased bone density (89). Remaining in a water-supported environment is appropriate if a dry environment exacerbates symptoms or if patients prefer water. Transition from a wet to a dry environment should occur if patients are doing well in the water but must return to land to meet functional training needs efficiently and attain their ultimate competitive goals (90).

The aquatic rehabilitation programs that will be reviewed are based on dynamic lumbar, thoracic, and cervical stabilization techniques that have been previously described for land programs (91–95). Dynamic land-based stabilization training is also referred to as segmental or core stabilization exercise. This

type of exercise program seeks to improve the neuromuscular control, strength, and endurance of muscles in the trunk, pelvic floor, thorax and cervical spine, theoretically helping patients gain dynamic control of segmental spine forces; eliminate repetitive injury to motion segments (i.e., discs, zygapophyseal joints, and related structures); encourage healing of injured motion segments; and possibly alter the degenerative process. The underlying premise is that motion segments and supporting soft tissues react to minimize applied stresses and reduce risk of injury (91–93). There are, however, few prospective studies on patients with low back pain and less discussion of patient selection, dose response, and long-term outcome with this type of rehabilitation construct (94,95). The goals of aquatic stabilization exercise and swimming programs incorporate these elements but take into account the unique properties of water so that risk of spine injury is reduced. Aquatic stabilization programs help develop patients' flexibility, strength, and body mechanics so that a smooth transition to aquatic stabilization swimming programs or other spine-stabilized activities may occur. Such programs can help first-time swimmers or patients who previously swam (96–99).

Graded elimination of gravitational forces through buoyancy allows patients to train with decreased yet variable axial loads and shear forces. In essence, water increases the safety margin of patient postural error by decreasing the compressive and shear forces on the spine. Gravitational forces may be further attenuated by using aquatic traction techniques for lumbar, thoracic, and cervical spine dysfunctions and pain (100). Velocity can be better controlled by water resistance, viscosity, buoyancy, and training devices. Buoyancy increases the range of training positions. The psychological outlook of athletes may be enhanced because rehabilitation occurs in their competitive environment. Many believe that pain attenuation takes place in the water because of the sensory overload generated by hydrostatic pressure, temperature, and turbulence (101).

### Aquatic Spine Stabilization Techniques

Although the spine stabilization principles discussed for land programs also apply to aquatic programs, certain exercises that can be performed on land cannot be reproduced in water and vice versa. Aquatic programs can be designed for patients who cannot train on land or for those whose land training has reached a plateau. Eagleston (97) first described aquatic stabilization in 1989.

Eight core aquatic stabilization exercises with four levels of difficulty have been developed to provide graded training of stabilization skills (97). Programs must be customized to meet the needs of each patient's unique spine pathology, related musculoskeletal dysfunctions, and comfort with the aquatic environment. Also, patients who have had joint replacements require particular care during positioning in the water because the replacements can change the center of buoyancy and may cause patients to sink due to high specific gravity (102). When a program is mastered, a more advanced program is provided. That said, there are numerous types of aquatic spine stabilization programs. All share at least one similar goal, to enhance dynamic stabilization. The aquatic spine specialist must be

aware of as many styles and types of aquatic stabilization programs as possible. They can then pick the most appropriate exercises from each program when creating an exercise regime that best meets their patient's needs (94).

Eventually, if a patient wants to incorporate a swimming program, a series of transitional aquatic stabilization exercises are initiated. These help to establish a spine-stabilized swimming style that minimizes the risk of further spine injury and helps maximize swimming performance (103).

### Spine-Stabilized Swimming Programs

Once a patient's stabilization skills have progressed to the point when swimming is possible, a thorough analysis of stroke technique and its effect on spine motion is critical (103). The following overview focuses on lumbar spine injury and indicates the role that the cervical spine plays in the mechanics of lumbar aquatic motion.

Similar to gait analysis, analysis of stroke mechanics should be performed in an ordered, sequential manner so that all deficits and their relationships are carefully and fully scrutinized. Typically, the analysis begins at the head and progresses distally.

### Prone Swimming

During prone swimming, the patient's head should be midline. Breathing should occur by turning the head (i.e., rotating

the head along the axial plane). There should be no craning (i.e., suboccipital cervical extension and rotation) or cervical extension and rotation (C2-C7). Body roll also contributes to proper breathing mechanics and is essential to minimize dysfunctional cervical positioning and subsequent pain. The cervical spine should be kept in the neutral position along the sagittal plane because excessive extension causes the legs and torso to drop in the water and excessive flexion can cause a struggle for air (103).

The upper-body arm position is evaluated by stroke phase. Freestyle is made up of three phases. The entry phase includes hand entry and hand submersion (ride). The pull phase incorporates insweep, outsweep, and finish components. The recovery phase includes the exit and arm swing. Several stroke defects can cause poor lumbar mechanics. If the arm abducts beyond 180 degrees, lateral lumbar flexion and rotation are produced. During the pull phase, decreased body rotation can cause lateral lumbar flexion and rotation that stress the lumbar motion segments, particularly the annular fibers surrounding the nucleus pulposus. Inadequate strength in the triceps during the finish phase results in low arm recovery, which in turn generates secondary lateral flexion and rotation through the lumbar spine. During recovery, inadequate body roll causes the neck to crane, which results in a struggle for air and accompanying lateral flexion and rotation through the lumbar spine (Table 62-2).

**TABLE 62.2 Freestyle Stroke Defects**

Primary Peripheral Joint Stroke Defect	Secondary Effect	Spine Reaction
Head high	Lower body sinks	Increased cervical extension Increased lumbar extension
Head low	Upper body sinks	Increased lumbar flexion
Crane breathing	Lower body sinks Contralateral shoulder sinks	Increased cervical and suboccipital extension Increased cervical rotation Increased lumbar lateral flexion and rotation
Crossover hand entry	Lateral body movement	Increased lumbar lateral flexion and rotation
Wide hand entry	Contralateral shoulder roll	Increased cervical rotation Increased lumbar lateral flexion and rotation
Inefficient pull power	Upper body sinks Difficulty breathing	Increased cervical rotation Increased cervical extension Increased lumbar extension Increased lumbar lateral flexion and rotation
Increased hip flexion	Decreased kick propulsion Lower body sinks	Increased cervical extension Increased lumbar extension Increased lumbar lateral flexion and rotation
Crossover kick	Decreased kick propulsion Increased hip roll	Increased cervical extension Increased lumbar extension
Increased knee flexion	Lower body sinks Decreased kick propulsion	Increased compensatory lumbar lateral flexion and rotation Increased cervical extension
Increased ankle dorsiflexion	Lower body sinks Decreased kick propulsion Increased hip roll	Increased lumbar extension Increased cervical extension Increased lumbar extension
	Lower body sinks	Increased compensatory lumbar lateral flexion and rotation

Data from Aquatechnics Consulting Group, Inc., Aptos, CA.

The aquatic environment provides numerous advantages to assist rehabilitation of patients with spine pain. A series of aquatic stabilization exercises has been designed that incorporates the intrinsic properties of water and enhances rehabilitative efforts. When these exercises are mastered, injured patients can soon advance to spine-safe swimming or other high-level aquatic training activities (104). Swimming programs, in particular (105–107), require that close attention be directed to proper swim-stroke biomechanics and to the effect that abnormal mechanics may have on the spine. This attention ensures the most rapid rehabilitation of painful spinal disorders.

### Neurologic Disorders

The advantages of the aquatic environment in the rehabilitation of neurologic disease have been noted for many centuries. Roosevelt's rehabilitation at Warm Springs, Georgia, is common knowledge. The use of pool exercises for spinal injury rehabilitation is a mainstay at many rehabilitation centers, and Sir Ludwig Guttman built a central focus for aquatics in the Spinal Injury Unit at Stoke-Mandeville. Throughout the United States, the Easter Seals organization has focused on the rehabilitation of children with cerebral palsy through pool-based programs. Programs have been designed for many neurologic diseases, and efficacy has been noted for multiple sclerosis (105–108), late poliomyelitis (109,110), and spinal cord injury (54,111,112).

From a technical standpoint, there is little difference in the aquatic techniques used in neurologic rehabilitation, with some disease-specific exceptions. Patients with multiple sclerosis may benefit greatly from aquatic programs, because of the ability of water to prevent core temperature increase during exercise, but the pool temperature should be cool to start, below thermoneutral. The authors have found ideal pool temperatures for patients with multiple sclerosis to be in the range of 25°C to 28°C (77°F to 82°F). There are literature reports of warmer temperatures being used with safety, but patient comfort should be an essential consideration (113). In contrast, spinal-injured patients lacking thermoregulatory capacity require much higher temperatures, in the range of 35°C to 37°C (95°F to 98°F). All neurologically impaired individuals obviously require close monitoring by poolside or in-water personnel. Patients with normal thermoregulatory ability and tolerance may be safely treated between 28°C and 35°C.

The techniques developed at Bad Ragaz and the methods developed by James McMillan, which have been called the Halliwick method because of their initial development and use at the Halliwick School for Crippled Girls in England, have been used extensively in the management of cerebral palsy rehabilitation. Their description is beyond the limitations of this chapter, but these methods are described thoroughly elsewhere (114,115). Essentially, the techniques use the properties of buoyancy, warmth, and careful body positioning to achieve reduction in muscle tone. The patient is floated through the use of buoyant rings to support arms, legs, and head as clinically warranted. These techniques are valuable in spinal injury rehabilitation as well and have been used in hemiplegia following stroke.

## TECHNICAL ISSUES

### Facility Options

#### Health Facility Pools

Aquatic facilities located within health-care facilities are generally warm-water pools, which usually cannot be adjusted for temperature, and are shallow, rarely exceeding a depth of 4.5 ft. They are usually in-ground pools. They often offer ramp access or may use slings to gain access for disabled individuals. The pools are usually small, because of constraints imposed by expensive space and construction. Although warm water is more comfortable for low-level activities and acute rehabilitation, it is not ideal for patients with multiple sclerosis, and it makes high-level activities exhausting. Pool size limits high-level activities as well, and often, group therapy must be done in small groups only. Staff is medically knowledgeable but often varies in aquatic skill. Facility-based pools are suitable for the acute rehabilitation of orthopedic populations, neurologic rehabilitation (with the exception of patients with multiple sclerosis), and arthritis rehabilitation. Common appropriate techniques include Bad Ragaz, Halliwick, aquatic spine stabilization, Red Cross arthritis, and low-level conditioning programs. Some health facilities also offer the Arthritis Foundation YMCA Aquatic Exercise Program, which has added adaptations for both deep-water and juvenile programs.

#### Community Pools

Community pools nearly always use cool water; vary in depth, often to 9 ft; usually offer stair or ladder access; and are in-ground designs. Varied depths make a wide range of programs possible, both horizontal and vertical, although the cool water precludes sedentary activities. Staff size is usually limited and without medical sophistication. These facilities are ideal for transitioning patients from the acute health facility pool, especially to group activities such as aquaerobics, low back classes, arthritis classes, or general conditioning. Because of access difficulty and cool water, they are often difficult for populations with severe physical limitations.

#### Hot Tubs, Spas, and Therapeutic Tanks

Hot tubs, spas, and therapeutic tanks usually feature hot water, are small and very shallow (rarely exceeding 3 ft in depth), and are often above-ground designs. Most offer added turbulence through jets and temperature adjustability through a narrow range. Although the high temperature is useful for acute treatments, patients quickly elevate their core temperatures even when not exercising. Hot tubs and spas are suitable for acute joint rehabilitation and relaxation; movements are limited. Staff is varied in skill level but often does not have a therapy background.

#### Deep-Water Environments

Deep-water environments, including therapeutic tanks, may be deeper and cooler and facilitate suspended activities for avoidance of weight bearing. These environments are very adaptable, permitting even high-level conditioning, including aqua-running, cross-country skiing, and ballet movements, if the temperature can be brought to an appropriate level.

Tethering may be used to stabilize the immersed individual during exercise. Swimming skill is not required, although tank use usually requires flotation and always requires immediate supervision. Deep-water facilities are ideal for athletic rehabilitation, rehabilitation of early fractures when weight bearing is precluded, and high-level conditioning activities. Staff tends to come from an athletic training background.

### Techniques in Current Use

#### Treatment Schools of Thought

Treatment schools of thought include Bad Ragaz (116,117), Halliwick (114,115), and Watsu (118,119). All these methods of aquatic therapy are techniques consisting of a developmental and progressive set of structured exercises. The first two are primarily intended for neurologic impairment, and the latter is an offshoot of shiatsu massage technique and was not originally developed for medical therapy, although more recently it has been found useful in the management of cerebral palsy (120).

### Specialized Equipment

#### Flotation Devices

A broad range of flotation devices have been developed for aquatic rehabilitation. For central trunk flotation, neoprene vests and foam waist belts are the most commonly used. Bad Ragaz techniques use foam rings that are placed around arms and legs or under the head. Kick boards, leg floats, vinyl foam flexible buoys, and combinations of the preceding are all important pieces of the aquatic rehabilitation armamentarium if a broad base of patients is to be treated.

#### Resistive Devices

As strengthening proceeds, the natural resistance of the water may be augmented through devices to increase the surface area of the moving part. Finned dumbbells, finned boots, kick boards, and flotation devices all may be used to add resistance to movement.

#### Performance Measurement Tools

Water is a more challenging environment for the therapist wishing to quantify performance. Waterproof heart rate monitors are useful, and as in the spine section, quantifying time, resistance, and movement freedom can add quantification (104,121). The authors have found standardized exercise log sheets to be useful. These sheets are completed during the treatment session and monitored during subsequent visits as well as in outpatient medical visits. If properly created, they may be used as a clinic progress note, providing support for reimbursement processes.

## SUMMARY

The decline in utilization of the aquatic environment has been to the disadvantage of patients. This environment offers significant benefit, a wide margin of therapeutic safety, and cost-effectiveness to a great variety of clinical situations. In a time of

scrutiny of health-care expenditures, it becomes critical to find safe, inexpensive treatment modalities for common problems. We must find methods that are suitable for self-management regimens, ideally across a large variety of clinical concerns and which may be easily learned by the patient. These methods should have the added advantages of high patient compliance and consistency. The aquatic environment offers a significant step toward these goals. Aquatic therapy is a scientifically grounded, useful approach to a broad range of rehabilitative problems from acute to chronic, and patients usually find it helpful and pleasurable. Although specific aquatherapeutic approaches are plentiful, many problems lend themselves to creative aquatic-based solutions as well. Successful rehabilitation may occur with a high safety margin and at low cost, especially when community pools are used, and professional extender personnel may be used for group programs, further decreasing cost while increasing regimen adherence (122).

# Therapeutic Physical Agents

This chapter reviews the physical agents with an emphasis on their clinical use, scientific basis, and effectiveness. Although the properties of many agents overlap, discussion will begin with superficial heat and cold and then progress to hydrotherapy, the diathermies, and electrical therapies. The chapter will conclude with an analysis of some of the less established modalities, such as lasers, monochromatic light, vibration, low-intensity electrical stimulation, and extracorporeal shock wave therapy.

## HEAT AND COLD

Heat and cold have potent effects on tissue. For example, temperatures above 42°C may be painful, and prolonged exposure to those above 45°C may cause injury (1). Temperatures below 13°C are also uncomfortable, and systemic temperatures below 28°C can cause death (1). In addition, metabolic and enzymatic processes are temperature dependent: an increase of 3°C increases collagenase activity severalfold (2). Heating the hands to 45°C reduces metacarpophalangeal joint stiffness 20%, whereas cooling them to 18°C increases stiffness by a similar amount (3). Temperature changes of a few degrees affect nerve conduction velocities, and changes of 5°C to 7°C alter blood flow (4–6) and collagen extensibility (7). In practice, most clinical treatments attempt to warm tissues to between 40°C and 45°C. As a point of reference, a gradual 20-minute immersion of the body in 22°C cold or 42°C warm baths result in core temperature changes of 0.3°C to 0.4°C (8). Cold therapy can produce intense local effects; ice treatment over an inflamed knee joint reduces skin temperatures by 16°C and intra-articular temperatures by 5°C or 6°C (9). Conversely, hot paraffin is reported to increase local skin temperature and knee intra-articular temperature by 7.5°C and 1.7°C, respectively (9). Although the heating modalities differ, most gain their effects by producing analgesia, hyperemia, changes in local or systemic temperatures, and reduced muscle tone. As a result, they share many of the indications (Table 63-1) and contraindications (Table 63-2) of heat in general (10). Cold's main effects are analgesia, reduced perfusion, and muscle tone reduction. As a result, cold has indications (Table 63-3) and contraindications (Table 63-4) that are often surprisingly similar to heat.

## Superficial Heat

Tissue can be heated or cooled by conduction, convection, or conversion. The first of these, conduction, requires the physical

contact of two or more objects at different temperatures. A hot pack in contact with a patient's back exemplifies conductive heating. The second, convection, also involves the transfer of energy between objects at different temperatures. In this case, however, one object, the medium, is moving relative to the other. Whirlpool baths are the most common convective heating modality. (Note that the medium in contact with the patient is in motion. As a result, the heating and cooling of the immersed body is more intense than would occur in a conductive situation with a stationary medium.) The last approach, conversion, involves the transformation of one form of energy to another. Heat lamps and ultrasound devices heat conversionally, since they rely on transformation of radiant or sound energy to heat.

The physical properties of superficial heating and cooling modalities differ, but none is able to overcome the combination of skin tolerance, tissue thermal conductivity, and the body's responses to produce temperature changes of more than a few degrees at depths of a few centimeters. The following sections review the characteristics of the most common superficial agents.

## Hot Packs

Hot packs (e.g., hydrocollator packs) typically consist of segmented cloth bags filled with a silicon dioxide that, when exposed to moisture, absorbs many times its own weight of water. These packs are available in various sizes and are stored in water bath reservoirs at temperatures of 70°C to 80°C. When needed, the packs are removed from the reservoirs and excess water is allowed to drain off. The packs are then wrapped in an insulating cover or toweling and placed on the patient (Fig. 63-1).

Hot packs are one of the most commonly used heat modalities (11) due to their advantages of low cost, minimal maintenance, long life (i.e., packs last as long as 5 years; reservoirs, up to 30 years), patient acceptance, and ease of use. A variety of home-use packs are available and many can be heated in a microwave oven.

Hot packs have few risks that are not outlined in Table 63-2. However, scalding is a possibility, and it is important that excess water is drained off before use, that the insulating pad/toweling is not wet, and that the pack is placed over, not under, the patient to avoid the body's weight expressing hot water out of the pack and wetting the insulation.

We often think of hot packs as the source of a relatively stable temperature. This is not necessarily true. Thus, although

Tenosynovitis  
Fibrositis  
Fibromyalgia  
Superficial thrombophlebitis  
Induction of reflex vasodilation  
Collagen-vascular diseases

hot packs maintain therapeutic temperatures throughout a treatment session, they cool significantly over the 20- to 30-minute period. At one time, this cooling tendency was used therapeutically. Kenny packs, for example, were thin wool cloths that were soaked in 60°C water and spun dry before use. After spinning, they contained little water and cooled rapidly. Consequently, they were replaced at 5- to 10-minute intervals and produced a cyclic heating pattern that was considered particularly effective for muscle pain and spasms of poliomyelitis.

Electric heating pads, hot water bottles, and circulating-water heating pads are alternatives to hot packs. Many of these do not cool spontaneously and not all have reliable timers or thermostats. Burns are possible and exposure may need to be limited in the elderly, people with diminished sensation, or those who may fall asleep during use.

### Heat Lamps

Radiant heat, although less frequently used than in the past, is a versatile and easy way to warm superficial tissue. Specialized

Reduction of local and systemic metabolic activity

infrared (IR) sources may be used due to their convenience and durability. However, incandescent lights release most of their energy as heat, and clamp lamps using these bulbs can both be used as an inexpensive alternative.

Skin temperatures are controlled by adjusting the distance between the heat source and the patient. Point sources such as light bulbs heat according to the “inverse square law”; that is, energy density decreases inversely in proportion with the square of the distance ( $1/r^2$ ). Elongated sources tend to follow a slower inverse distance ( $1/r$ ) relationship. Heating is most intense when a source is perpendicular to the patient and decreases in proportion to the cosine of the angle between the beam and the perpendicular. In practice, heat sources are typically placed directly above, and about 40 to 50 cm from, the patient.

### Choice

The physiologic effects of dry heat from a heat lamp differ little from those of moist heat of a hot pack (12). As a result, the choice depends on ease of use and preference. If the patient is in bed or cannot tolerate pressure, radiant heat may be a better option. Similarly, if a patient prefers moisture, the choice is also easy.

### Safety

The precautions in Table 63-2 apply to the superficial heating agents (10). In addition, these modalities can burn the patient and, with chronic use, may produce a permanent brown skin discoloration (erythema ab igne).

**TABLE 63.4** General Precautions and Contraindications for Therapeutic Cold

Ischemia  
Cold intolerance  
Raynaud's phenomenon or disease

Cold allergy  
Inability to communicate or respond to pain  
Poor thermal regulation  
Cutaneous insensitivity

**FIGURE 63-1.** Hot pack treatment of the low back. The pack is covered with an insulated wrapper and separated from the patient with several layers of toweling. Note that the patient must be positioned carefully and be able to tolerate the weight of the pack.

### Effectiveness

As noted above, superficial heat and cold have clear and established effects of a variety of physiological, metabolic, and tissue effects. As such, their main use has been for the amelioration of discomfort and, to a lesser extent, the control of swelling and edema. Given their limited penetration, usage is usually restricted to the musculoskeletal system where there is support of benefits for its use as an adjunct to the treatment of a variety of musculoskeletal conditions such as low back pain (13,14), contractures (15), and rheumatoid arthritis (16).

### Hydrotherapy

Hydrotherapy uses fluid to transfer thermal energy and mechanical forces to tissue. Whirlpool baths (Fig. 63-2) and

**FIGURE 63-2.** Whirlpool treatment of the lower extremity. Water temperatures may range from 11°C to 43°C, depending on the patient's condition and the amount of surface area treated. Positioning as well as entering and leaving the bath are facilitated with a hydraulic chair.

**FIGURE 63-3.** Hubbard tank treatment. These tanks are large, are expensive to operate, and occupy large amounts of floor space. Nevertheless, they are necessary for the cleaning of large wounds and helpful in treating patients with conditions involving multiple joints.

Hubbard tanks (Fig. 63-3) use agitated water to produce convective heating, cooling, massage, and gentle debridement. Agitation, however, is not essential, and sitz baths, paraffin baths, and contrast baths all use a stationary medium. Immersion itself has effects. Subjects placed in water up to their chins will have transient elevations of their serum atrial natriuretic protein that are independent of temperature and result from increased venous return or right atrial loading (17). This section discusses hydrotherapy as well as other alternatives, such as balneotherapy and fluidotherapy.

### Whirlpool Baths and Hubbard Tanks

Tanks vary in size from small portable whirlpools designed to treat a single extremity to Hubbard tanks containing thousands of liters. Pools and tanks are not always essential; hand-held shower heads and small water jets are often used for local treatment such as the irrigation and debridement of deep wounds and burns.

Temperature choice depends on the amount of immersion, treatment goals, and the patient's medical condition. Neutral temperatures of 33°C to 36°C are usually well tolerated on limited portions of the body, although for a healthy patient, temperatures of 42°C to as much as 45°C or 46°C are possible. Full-body immersion for 20 minutes can increase systemic temperatures by 0.3°C (8); Hubbard tank temperatures are usually limited to 39°C. Temperature selection should take into account the fact that for any given temperature, turbulent water heats and cools more vigorously than stationary water.

Whirlpools and Hubbard tanks are well suited for wound and burn treatment in which gentle agitation, heat, and solvent action are needed. Neutral temperatures (to somewhat warmer, depending on comfort) are chosen. Once the patient is immersed, agitation is increased to provide gentle debridement and aid in dressing removal.

“Sterile” tanks should be specified for burns and wounds. Although true sterility is not possible, a sufficient approximation is possible to make disease transmission unlikely. If wounds are large or if there is a significant exposure of internal tissue, sodium chloride may be added to the water (5 kg or more for a Hubbard tank) to improve comfort and lessen the risks of hemolysis and electrolyte imbalance. Additional agents such as potassium permanganate and gentle detergents may be added as desired.

Hydrotherapy is a common adjunct to the treatment of rheumatoid arthritis, “muscle spasm,” and joint stiffness after cast removal. Immobilized patients and those with wounds often find the concept frightening, and treatment should be reviewed before the first session with an emphasis on its comfort, transfers, and any use of plinths and hoists.

Hydrotherapy is resource intensive, expensive, and consumes large amounts of hot water and floor space. As a result, therapy clinics are tending to discard their larger units and to use the smallest baths possible.

### Contrast Baths

Contrast baths use two reservoirs, one is typically at 38°C to 40°C and the other significantly cooler at about 13°C to 16°C. The theory of their use is that the alternating exposure to heat and cold results in a reflex hyperemia and neurological desensitization. Treatment typically begins with the distal extremity placed in the warm bath for about 10 minutes and then proceeds to four cycles of alternating 1- to 4-minute cold and 4- to 6-minute warm soaks. If edema is an issue, a case can be made for ending with a cool, rather than a warm, soak.

Contrast baths may be most commonly used in treatment programs for rheumatoid arthritis and complex regional pain syndrome I (CRPS I). People with rheumatoid arthritis often benefit but may find simple warm-water soaks as effective and less difficult. Patients with CRPS I may prefer to begin with less extreme bath temperatures and also seem to benefit, but this improvement is difficult to separate from the effects of other desensitization and activity measures. There is limited evidence to suggest that contrast baths may also improve autonomic regulation and blood pressure in people with hypertension (18); research findings in other popular areas of application such as sports medicine are limited (19).

### Sitz Baths

Warm sitz baths are enshrined in the treatment of hemorrhoids, anorectal fistulas, and postpartum pain. While there has been criticism about the limitations of our knowledge of sitz bath effectiveness (20), the available research provides support for this practice. For example, sitting in water between 40°C and 50°C (with warmer temperatures perhaps more effective) lessens sphincter activity and anal pressures in normal subjects as well as those with hemorrhoids and anorectal fistulas (21). A recent trial following anal surgery found those receiving sitz baths obtained pain relief equivalent to that produced by oral analgesics (22,23). While research provides limited reports of side effects, there is, as with any heat and

water modality, a risk of scalding and perineal burn at higher temperatures (24).

### Edema

The ancient Greeks and 18th-century physicians treated edema with water immersion, a practice mimicked today with compressive sleeves. Research supports this intuitively reasonable treatment; immersion increases natriuretic proteins (17) and renal water and salt loss in normal subjects as well as those with the nephrotic syndrome and cirrhosis (25). Because warmth produces a reactive vasodilation, neutral temperatures appear to be the most effective.

### Water-Based Exercise

Water-based exercise and therapeutic pools are a popular way to provide gentle, progressive exercise in a setting that permits limited weight bearing. The approach has shown benefits (26), but its value over land-based programs has been more difficult to establish. Although patients with rheumatoid and osteoarthritis often like the warmth and support of water-based exercise, benefits may not be as clear as they might seem. For example, a number of studies involving land- and water-based programs have found that water-based programs provide little or no benefits over their land-based counterparts for patients with osteoarthritis, rheumatoid arthritis, juvenile inflammatory arthritis, and anterior cruciate rehabilitation (27–29). Although many believe exercise is beneficial for patients with fibromyalgia, the benefits of water- over land-based approaches remain unclear (30–34).

### Balneotherapy

Balneotherapy (spa) therapy is now little more than a curiosity in North America. In Europe, however, acceptance remains strong and visits to spas are supported by some governments and insurance programs (35). Treatments involve a combination of physical therapy, water baths, mud treatments, mineral water consumption, and education that may take place in a resortlike atmosphere for periods as long as 3 weeks. The fundamental tenet of the approach is the belief that water containing dissolved gases (such as nitrogen and carbon dioxide), elements (e.g., calcium, magnesium, zinc, and cobalt), and compounds (e.g., hydrogen sulfide) has therapeutic effects.

Balneotherapy research has traditionally been hampered by poor quality and an environment in which a patient is undergoing multiple changes in his or her lifestyle and exercise patterns. Research quality is improving, however, and higher quality controlled studies are becoming available. Furthermore, although intact skin is relatively impervious, we know that blood concentrations of substances such as bromine and rubidium may be increased after bathing in patients with impaired skin barriers (36,37).

Although most U.S. physicians are skeptical, some controlled investigations support the use of balneotherapy for the inflammatory and degenerative arthritides. For example, although the differences are often small, patients with rheumatoid arthritis, ankylosing spondylitis, and osteoarthritis appear

to respond similarly to or somewhat better than they do to alternative treatments (35,36,38–46). There are many studies, but there is limited evidence that patients with nonradiating low back pain may do better following balneotherapy than a control treatment (47). In all, balneotherapy studies are often limited by poor size, incomplete blinding, and short follow-up. Nevertheless, the findings are intriguing and warrant honest consideration.

### Fluidotherapy

Hydrotherapy usually uses water as the heat-exchanging medium, but substances such as pulverized corncobs and small beads “fluidized” by hot air jets may be substituted. Although these devices have been available since the 1970s, the benefits of this high-temperature, low-heat capacity approach over other approaches for improving joint mobility and sensory desensitization remain controversial (48).

### Safety

The general precautions of heat (Table 63-2) apply to hydrotherapy. Drowning, cardiac disease, systemic hyperthermia, and disease transmission are also concerns, but they may be overemphasized. Hot water–associated seizures are rare but are known to occur (49).

Cardiac disease may not be an absolute contraindication to hyperthermia as was once thought. For example, even though sauna baths (80°C to 100°C) elevate body temperatures by 1°C or 2°C (50,51), research indicates that they may improve the function and quality of life of individuals with severe congestive heart failure (CHF) (52). Furthermore, Finnish heart attack survivors return to sauna bathing without apparent increased risk, and 15-minute soaks in 40°C hot tubs do not create ischemic electrocardiogram changes or alter systolic and diastolic blood pressures more than cardiac rehabilitation–associated stationary bicycle exercises (50,51,53).

Hydrotherapy-associated infections seem to be rare. However, there may be some reproductive consequences: neural tube defects may be increased (relative risk, 2.6 to 2.9) in the children of women who take sauna baths during early pregnancy (54), and sperm counts may be lowered after isolated or repeated sauna sessions (55).

### Paraffin Baths

Paraffin baths are thermostatically controlled reservoirs filled with a 1:7 mixture of mineral oil and paraffin. Bath temperatures (45°C to 54°C) are higher than in most hydrotherapy but are well tolerated because of the low heat capacity of the mixture and the tendency for an insulating layer of wax to build up on the surface of the treated area.

Two paraffin treatment approaches predominate. Dipping is the most common and consists of the patient submerging the treated extremity in the bath ten times, with pauses between dips to permit a layer of paraffin to solidify. The treated area is then covered with a plastic sheet and placed in an insulating cover for about 20 minutes (Figs. 63-4 and 63-5). The paraffin is then stripped off and returned to the container.

**FIGURE 63-4.** Paraffin bath treatment. Two approaches are common. In the dipping technique, the extremity is immersed in the bath, removed briefly to allow the wax to solidify, and redipped for a total of ten repetitions. After the dipping, the extremity is wrapped in an insulating cover for about 20 minutes before the wax is removed. The immersion technique provides a more vigorous heating and is similar to the dipping approach, except that after a number of dips, the extremity is kept immersed in the paraffin.

Dipping initially increases skin temperatures to about 47°C, but by the end of a 30-minute session, skin temperatures fall to within a few degrees of baseline. Deeper tissues respond to a lesser extent; subcutaneous temperatures may increase by 3°C, and intramuscular/intra-articular temperatures may increase by 1°C (56).

**FIGURE 63-5.** Paraffin-dipping technique. After completion of the dipping, the extremity is placed in a plastic-coated, insulated bag to slow cooling. As an alternative, the hand may be wrapped in a plastic sheet and taping.

Continuous immersion is an alternative approach in which the treated extremity is dipped six to ten times in the paraffin and then kept immersed for 20 to 30 minutes. Heating is more intense with this method but is still well tolerated because a layer of insulating solidified paraffin forms on the skin. Immersion produces the same initial maximum skin temperature as dipping; however, temperatures decrease less rapidly. At the end of a session, skin temperatures are about 41.5°C with subcutaneous and superficial intramuscular temperature increases (about 5°C and 3°C, respectively), which are higher and more persistent than what occurs with dipping (56). The dip-and-wrap method in conjunction with limb elevation is preferable if the patient is predisposed to edema.

Paraffin baths are often used to treat hand contractures associated with rheumatoid arthritis, scleroderma, burns, and injury. Dipping or immersion is the most common technique, but, at times, paraffin may be brushed on difficult-to-treat areas. Reports in the literature are scant, but these messy treatments seem frequently to be helpful and capable of producing significant temperature changes and improvements in joint mobility (9,48,57).

### **Safety**

A thermometer should be kept in the reservoir, and paraffin temperature should be checked (typical values are about 48°C) before use to ensure that the paraffin is at the correct temperature and to avoid burns. (A film of solidified wax around the margins of a reservoir is a sign that the temperature is not dangerously elevated.) Small commercial units are available for home use. If the feet have poor circulation, a few insulating layers of paraffin may be brushed on before they are dipped or immersed.

Most clinicians do not heat acutely inflamed joints and tissues vigorously because even a few degrees of temperature elevation (as may occur with paraffin baths or hot soaks) increases intra-articular enzymatic activity (2). Although there has been controversy about its appropriateness, warmth clearly improves comfort, and most clinicians use superficial heat in the subacute situation.

### **Diathermy**

There are three diathermy (literally “through heating”) agents: ultrasound, shortwave diathermy, and microwave diathermy. Ultrasound is the most commonly used of the three, but shortwave diathermy, despite a gradual decline, is still in use as is pulsed shortwave (which is claimed to be athermic). Microwave diathermy no longer has a place in routine therapy practice but continues to have specialized medical applications. All three will be reviewed but with a declining emphasis commensurate with their current use.

### **Ultrasound**

Ultrasound is sound that occurs at frequencies above the 17,000- to 20,000-Hz limit of human hearing. As such, it shares the characteristics of sound in general: its waves consist of alternating compressions and rarefactions; it requires

a medium for transmission; it transmits energy; and it can be focused, refracted, and reflected. Although arguments are made for a variety of frequencies, most therapeutic ultrasound treatment occurs between 0.8 and 3 MHz due to the practical considerations of focusing, penetration, and standardization.

### **Biophysics**

Ultrasound has both thermal and nonthermal effects. Heat production, with its goals of hyperemia, enhanced soft-tissue extensibility, and lessened pain and muscle tone, is the best known. Nonthermal processes—which include cavitation, streaming, standing waves, mechanical deformation, and shock waves—may also be sought because of their ability to alter cell membrane permeability and function (58). The first of these nonthermal processes, cavitation, occurs when high-intensity ultrasound passes through a liquid and produces small bubbles that may either rhythmically oscillate in size (stable cavitation) or grow and abruptly collapse (unstable cavitation). In either case, large temperature and pressure changes may occur (59) and produce localized tissue distortion and injury. Pressure asymmetries produced by the presence of an ultrasonic beam can generate large shear forces that in turn may lead to media movement (streaming, microstreaming), tissue damage, or accelerated metabolic processes (58,60). Standing waves are generated from the superposition of sound waves and produce fixed regions of high and low pressure at half-wavelength intervals (which for 1 MHz ultrasound [tissue velocity 1,500 m/s] is about 0.75 mm) (61). Graphic effects are possible; ultrasound exposure produces repetitive bands of red blood cells in chick embryo vessels (62).

Ultrasound penetration into tissue depends on a number of factors. Frequency is particularly important as penetration decreases by a factor of 6 as the frequency increases from 0.3 to 3.3 MHz (63). Orientation is also critical. For example, about 50% of a 0.87-MHz ultrasound beam penetrates 7 cm in a direction parallel to muscle fibers, but the same beam penetrates only 2 cm in a transverse direction (63). Tissue type is also significant. Fifty percent of an ultrasound beam penetrates several centimeters in muscle, only a few tenths of a millimeter in bone, and 7 to 8 cm in fat (63,64). In practice, 3-MHz ultrasound is used for superficial tissues such as those of the hand and temporomandibular joint, as most of its energy is absorbed within 1 to 2 cm of the skin's surface. Lower frequency beams are used when deeper penetration is desired.

Ultrasound treatments are frequently delivered to anisotropic tissue, and it should be remembered that localized areas of temperature elevations of 5°C or more may occur at sound absorption discontinuities such as those that occur at bone–soft-tissue interfaces (63–65). Heat is lost from tissue as the result of conduction and cooling effects of the local blood flow.

### **Equipment**

Ultrasound machines typically use ferromagnetic lead zirconate titanate (PZT) ceramics to convert electrical energy into sound. Machines are increasingly computerized, and in addition to

indicating treatment time, wavelength and waveform are now often provided with predesigned treatment programs. Additional capabilities such as waveform modulation and concurrent electrical stimulation are also common.

Ultrasound frequencies are relatively stable and usually remain within 5% of the manufacturer's specifications (66,67). Machines, however, should be routinely calibrated as output powers and intensities (power output divided by the active area of the applicator) may vary by 20% or more during a session and as a unit ages (66,67).

### Technique

There are two philosophies of ultrasound therapy. The most widely held is that ultrasound's benefits are due to heating. This approach typically uses an unmodulated, continuous-wave (CW), or high-intensity pulsed beam with intensities of 0.5 to 2.5 W/cm<sup>2</sup>. The second approach emphasizes ultrasound's nonthermal properties. In this case, the beam is modulated to deliver brief pulses of high-intensity ultrasound separated by longer pauses of no power and as a result lower average energy intensity. Thus, heating is minimized and ultrasound's nonthermal effects are emphasized.

Ultrasound is usually delivered by moving the applicator (Fig. 63-6) over the treated area in slow (1 to 2 cm/s), overlapping strokes. Treatments cover areas of about 100 cm<sup>2</sup> and last 5 to 10 minutes. Indirect ultrasound, while less common, is used to treat irregular surfaces such as the foot and ankle where it is difficult to keep the applicator in contact with the skin. In these situations, the body part is placed in a container filled with degassed water. The applicator is held a short distance away (0.5 to 3.0 cm) and moved without touching the skin. Power intensities may need to be higher due to transmission losses.

Coupling between the applicator and the skin is not a trivial issue. The treatment area should be cleansed before

treatment, and a coupling agent is necessary. Degassed water (water that has been allowed to sit for several hours) is used for indirect ultrasound because the dissolved gases in water fresh from the tap form bubbles during treatment and attenuate the beam. Little practical difference exists between commercial gels and mineral oil for direct applications, with transmissivity similar to that for degassed water (68). However, mineral oil becomes watery and most people use the commercial products because of the convenience. Coupling agents should not be salt based (e.g., those used for EMG or ECG), as the salt may damage the applicator.

Phonophoresis is a variant of ultrasound in which biologically active substances are combined with the coupling medium in the hope that the ultrasound will force the active material into tissue. Although this technique has been in use since the 1960s, neither its effectiveness, penetration, optimal frequency, appropriate coupling mediums/active materials nor amount of material lost to the subcutaneous circulation is well established. Although claims of increased cortisol concentrations at depths of several centimeters after corticosteroid phonophoresis have been made, our own research as well as that of others (69,70) finds limited evidence for deep penetration. Clinical reports are mixed. Thus, although some clinical studies report phonophoresis with a variety of agents successful in terms of improved shoulder range of motion and pain following the treatment (71) as well as in the treatment of keloids and sarcoid nodules (72), other work involving an assortment of musculoskeletal conditions may find the approach no more effective than ultrasound alone (73).

### Indications

**Musculoskeletal Conditions.** The research relating to musculoskeletal condition is surprisingly inconclusive (74). For example, a study of 63 patients with calcific shoulder tendonitis treated with pulsed ultrasound (0.89 MHz, 2.5 W/cm<sup>2</sup>) found that the treated patients had significantly larger improvements in their pain and decrease in calcium deposits relative to their sham controls at the end of an intensive 6-week treatment program. However, this difference had disappeared at follow-up 9 months later (75). Although ultrasound may be more beneficial than corticosteroid injection in the treatment of shoulder pain, other studies and reviews find it no more effective than placebo or nonsteroidal anti-inflammatory medications for a variety of conditions ranging from subacromial bursitis or lateral epicondylitis (76) to heel pain (77). More tellingly, perhaps, an evidence-based practice guideline panel came to the conclusion that although therapeutic ultrasound was effective in the treatment of calcific tendonitis of the shoulder, there was no compelling evidence of its clinical benefits for other sources of musculoskeletal pain (78). Although these studies raise legitimate issues about its effectiveness in such conditions, many physicians and therapists remain convinced that ultrasound is useful for the treatment of at least some musculoskeletal pain. In support of this, several reviews have found evidence of some benefits in the form of increased motion and lessened stiffness from the cautious use of ultrasound in

**FIGURE 63-6.** Direct-contact ultrasound treatment of the elbow. Note the use of a folded towel to support the patient comfortably. Although not shown in the picture, a coupling agent is needed to acoustically couple the applicator and the skin.

patients with rheumatoid arthritis (79–81). A recent small scale study of ultrasound treatment of myofascial trigger points found significant pain relief from conventional relative to low-intensity ultrasound stimulation (82).

**Contractures.** Ultrasound is effective in increasing the range of motion of the heel cords, periarthritic shoulders, and contracted hips (83,84). In fact, due to its penetration and focusing capabilities, it is the only agent that can significantly heat (by 8°C to 10°C) the hip joint (65). Hand and Dupuytren contractures also may benefit from ultrasound (85), although a small study of burns did not find treatment beneficial (86). Collagen and tendon extensibility increases as temperatures increase and decreases as tissue cools. As a result, stretching should begin during heating and should continue as the tissue cools and “sets.”

**Soft-Tissue Wounds and Inflammation.** Ultrasound treatment of wounds and inflammation is based on the belief that either its heat (by increasing blood flow, metabolic, or enzymatic activity) or nonthermal effects (perhaps by changing cell wall permeability) accelerate healing. Laboratory studies offer some support (87). Human studies, however, provide a more mixed picture with a recent review of decubitus ulcers concluding that the evidence was too weak to assess (88). Some feel that inflammation and swelling are indications for ultrasound. Others believe that the heating and membrane permeability changes associated with treatment prohibit its use in acutely inflamed conditions such as in recent trauma and active rheumatoid arthritis.

**Trauma.** Although ultrasound may aggravate tissue damage and swelling if used too soon after an injury, subacute hematomas (89) and postpartum perineal pain (90) may improve more rapidly with treatment. Ankle sprains are a common indication for ultrasound treatment. Even here, benefits are unclear with a systematic review involving more than 570 patients concluding that current evidence, at best, supported the presence of limited benefit (74). A number of clinical and animal studies find evidence that ultrasound at intensities on the order of 1 W/cm<sup>2</sup> may provide at least short-term benefits in the treatment of symptomatic carpal tunnel syndrome (91,92). Although these reports are intriguing, benefits are not always evident and remain controversial (93).

**Fractures.** Low-intensity ultrasound improves the repair of bony injuries (94). For example, 30 mW/cm<sup>2</sup> pulsed 1.5-MHz ultrasound accelerates the healing of closed and open grade 1 fractures (95,96). Although ultrasound is not typically used for this purpose, its use has been approved by the Food and Drug Administration (FDA) for the treatment of some fractures. In view of the fact that 5% to 10% of fractures heal slowly (97), there may be a wider applicability for this treatment in the future.

**Other Indications.** Postherpetic neuralgia is often resistant to conventional treatment. Treatment with both pulsed and continuous 1- to 1.5-MHz ultrasound has been evaluated. Unfortunately, the studies have again often been poorly controlled, and the results are unclear; some investigators have found improvement (98,99), whereas others have not

(100). As ultrasound has thermal, and possibly nonthermal, effects on nerve conduction (101), further evaluation seems appropriate. Plantar warts, keloids, scars, and even chronic sinusitis are additional refractory conditions for which pulsed and conventional ultrasound has inconclusive benefits (102–104).

### ***Precautions and Contraindications***

Ultrasound produces intense heating and, under some conditions, potentially destructive nonthermal effects, such as shockwaves, cavitation, and media motion. The precautions in Table 63-2 should be heeded. In addition, fluid-filled cavities such as the eyes and gravid uterus are avoided due to the risks of cavitation and heat damage. The heart, brain, cervical ganglia, tumors, acute hemorrhage sites, ischemic areas, pacemakers, and infection sites should not be treated for obvious heat, neurophysiologic, and mechanical reasons. The spine should not be exposed to high intensities, and laminectomy sites, in particular, should be avoided. Ultrasound is used in children, although many are concerned about the effects of excessive energy and warmth on immature growth plates. As noted above, ultrasound is not used over acutely inflamed joints or tissues due to the fact that temperature elevations can increase enzymatic activity (105,106).

A common concern is that ultrasound treatment over metal implants in muscle or next to bone will elevate tissue temperatures to a higher level than would occur in their absence (107,108). The concept is certainly valid and although some studies found the effect smaller than might be expected, only a limited number of objects and geometries were studied. Although clear indications and contraindications do not exist, many simply avoid using ultrasound near metal.

### ***Shortwave Diathermy***

Shortwave diathermy (SWD) heats tissue with a combination of induced electrical currents and the vibration it imposes on the molecules of a tissue. Since SWD produces radio waves that can cause electrical interference, the U.S. Federal Communications Commission (FCC) has restricted its industrial, scientific, and medical use to 27.12, 13.56, and 40.68 MHz (wavelengths of 11, 22, and 7 m), respectively. Most SWD machines operate at 27.12 MHz.

### ***Biophysics***

Radio waves are absorbed as they pass through tissue, but actual penetration depths depend on the specifics of tissue as well as the frequency and characteristics of the applicator. Inductive applicators induce electrical (“eddy”) currents in tissue and, as a rule, produce the highest temperatures in water-rich, highly conductive tissues such as muscle. Capacitively coupled applicators, on the other hand, emphasize electric field heating. Maximum temperatures tend to occur in water-poor substances, such as fat, ligaments, tendons, and joint capsules (109). Significant heating is possible. Although effects depend on the dosage and application approach, SWD can increase subcutaneous fat temperatures by 15°C and

3- to 5-cm deep intramuscular temperatures by 4°C to 6°C (110,111).

SWD machines may produce pulsed as well as continuous wave (CW) output. CW diathermy is used when the treatment goal is heating. In contrast, pulsed shortwave diathermy, sometimes termed pulsed electromagnetic energy (PEMF), alternates brief periods of high power with longer periods of no power output. The average output power may be the same in both approaches, but, as is true with ultrasound, the pulsed approach may be chosen to emphasize nonthermal effects. Some investigators, for example, believe that certain pulse frequencies, even at low intensities, can increase blood flow and have resonant effects on cell function. Although nonthermal SWD phenomena (e.g., pearl chains) have been known for more than 40 years, their clinical benefits remain elusive.

### Technique

A SWD machine is essentially a radio transmitter that is tuned in the same way that any transmitter is tuned. The patient is in the machine's field and is protected from injury by tuning the circuit (automatically in modern machines) for maximum coupling. Once coupling is maximized, movement can only reduce heating. Two treatment approaches are possible. In one, the shortwave diathermy machine transmits radio waves that induce electrical currents in tissues in the same manner as currents would be induced in a radio antenna (Fig. 63-7A). These eddy currents, in turn, are degraded into heat as they flow in the body by the tissue's electrical resistance. In the second, the tissue to be heated is placed between two plates that are con-

nected to the SWD machine's output and serves as the dielectric of a capacitor (Fig. 63-7B). In this case, heating currents are produced as the radio wave polarity oscillates across the plates.

There are a variety of inductive applicators (see Fig. 63-7B). Drum applicators consist of coils encased in rigid containers that may be positioned with hinges around the body. Pad applicators are commercially available, semiflexible mats containing a coil that is connected to a shortwave diathermy machine and placed against the patient. Pads may have dimensions of 0.5 × 0.75 m and typically are used to treat broad areas such as the low back. Cable applicators consist of rubber-coated cables that were wrapped around an extremity or laid over the body. Cables were once common, but because of safety concerns and the need for careful placement, they have been replaced by drums and pads.

In the most common capacitive arrangement, the patient is placed between two platelike electrodes (see Fig. 63-7A). Rectal and vaginal applicators were once used in the treatment of pelvic inflammatory disease and chronic prostatitis, but due to improvements in antibiotics, are now seldom used or have been replaced by externally applied SWD or ultrasound. Recent research has shown variable benefits from SWD while no additional benefit for back pain over exercise and advice was found in large randomized controlled trials (RCTs), another investigator reported that treatment produced significant reductions in pain and synovial thickness in subjects with chronic knee synovitis (112,113).

Ultrasound can produce deep heating due to its easy use, and high availability is often substituted for SWD. This

**FIGURE 63-7.** **A:** Shortwave diathermy treatment using a capacitive plate arrangement. Careful positioning is necessary. The patient should wear no jewelry and lie on a nonconductive table. **B:** Shortwave diathermy treatment using an inductive applicator. Note the capacitive plate to the side and the emergency cutoff switch in the patient's hand. Again, metal is avoided, and the patient is carefully positioned on a nonconducting surface.

substitution may at times be inappropriate, as shortwave diathermy is less labor intensive and can warm larger areas than ultrasound.

### Microwave Diathermy

Electromagnetic radiation can be well focused when the wavelength of the radiation, as is the case with microwave diathermy, is comparable with the dimensions of the antenna. The FCC-approved industrial, scientific, and medical frequencies for microwave diathermy are 915 and 2,456 MHz (33- and 12-cm wavelengths, respectively).

### Biophysics

Microwaves do not penetrate tissue as deeply as shortwaves and ultrasound, but, like them, penetration decreases as frequency increases. Similarly, focusing becomes more difficult at longer wave lengths (110).

Microwaves are absorbed by water and should theoretically preferentially heat muscle. However, fat usually overlies muscle and absorbs a significant portion of the beam. As an example, at 915 MHz, subcutaneous fat temperatures may increase by 10°C to 12°C, whereas 3- to 4-cm-deep muscles will be heated only 3°C to 4°C (114).

### Technique

Microwave diathermy was often used to heat superficial muscles and joints such as the shoulder and speed hematoma resolution (115). Today, its use is rare although there are interesting reports of its use as an adjunct to potentiate the effects of cancer chemotherapy and radiation treatment (116).

### Precautions and Contraindications

The general contraindications listed in Table 63-2 apply to short- and microwave diathermy. Additional restrictions stem from their electromagnetic nature. For example, perspiration is conductive and, if present in a field, heats the skin. Metal produces localized heating in a field; patients should not wear jewelry, and treatment is given on a nonconductive table. Pacemakers, stimulators, surgical implants, contact lenses, and the menstruating or pregnant uterus should not be exposed to shortwave diathermy or microwave diathermy. Although many of these concerns seem almost academic, this is not always the case. For example, an inadvertent application of pulsed diathermy to the jaw led to a persistent vegetative state in a man with a deep brain stimulator (117). Some believe that small, metallic surgical clips or metallic intrauterine devices do not produce significant localized temperature elevations. This may be correct, but at least one study found that 1-cm wires positioned to mimic a surgical site produced temperature elevations during diathermy that were 3°C to 4°C greater than those that occurred in their absence (116). Many investigators follow a rule of “no metal” when using any diathermy. Microwaves selectively heat water, and its effects on the fetus are unknown. Treatment of edematous tissue, moist skin, the eyes, fluid-filled cavities, and blisters can produce unacceptable temperature elevations and cataracts.

**TABLE 63.5 Therapeutic and Environmental Magnetic Fields (T)<sup>a</sup>**

Typical residential exposure (199)	0.4
Earth's magnetic field	25–65
Automobile interior (221)	2
Subway passenger compartment (222)	16–64
Standard therapeutic magnet	250–5,000
Credit card erasure (223)	5,000
Pulsed electromagnetic field devices (224)	2,000–8,000
Bone growth stimulator	5,000
Exposure limits (continuous) (225)	
Occupational	$2 \times 10^5$
General public	$4 \times 10^4$
MRI	$1.5+ \times 10^6$

<sup>a</sup>1 Tesla = 10 Gauss.

Workplace safety is always an issue with electromagnetic devices. The situation, however, has been well addressed by the American National Standards Institute (ANSI) guidelines for workplace-associated exposure (118). As fields fall rapidly with distance and therapists work only intermittently with these agents, their exposures seem to fall well within these guidelines.

Epidemiologic studies seem to support the workplace safety of these electromagnetic diathermies. While it has been reported that miscarriage rates are increased or birth weights reduced in female therapists exposed to diathermy (119,120), there is no evidence of detrimental effects on the children of therapists working with these agents (119,121,122). Tables 63-5 and 63-6 display typical electromagnetic exposures and contraindications for use.

The use of any diathermy on an acutely inflamed joint is controversial. Thus, while patients have reported that treatment

improves comfort and some investigators feel that synovial temperature elevations to 42°C or more denature enzymes and produce a “thermal synovectomy” (123), most clinicians remain skeptical and avoid diathermy in this situation. As noted earlier, a similar, but less marked, controversy also surrounds the use of superficial heating for these situations.

### Cold (Cryotherapy)

Chilling a limited portion of the body produces local and distant physiologic effects. If the cooling agent is ice, skin temperature initially decreases rapidly and then more slowly approaches an equilibrium of about 12°C to 13°C in 10 minutes. Subcutaneous temperatures fall more slowly and decrease by 3°C to 5°C at 10 minutes. Deeper, intramuscular temperatures decrease the least and after 10 minutes have dropped a degree or less (124). Chilling for longer periods generates more pronounced cooling with intramuscular forearm temperature decreases of 6°C to 16°C after 20 minutes to 3 hours of cooling (6,9) and intra-articular knee temperatures decreasing 5°C to 6°C over a 3-hour period of cooling with ice chips (9). It should be remembered that although superficial tissues cool more rapidly than their deeper counterparts, specifics vary, depending on the nature of the cooling agent and the body's physiologic responses.

Cooling produces an initial period of vasoconstriction that may (125) or may not be followed by a reactive vasodilation (125–127). Vasoconstriction becomes evident within 5 minutes of cooling, and after 25 minutes of packing a knee in ice, soft tissue and bone blood flows are decreased by 30% and 20%, respectively (9). Superficial cold also decreases metabolic activity and with prolonged application lessens muscle tone, inhibits spasticity (128), increases gastrointestinal motility (129), slows nerve conduction, and produces analgesia (130).

### Technique

Ice packs, ice massage, iced compression wraps, and slushes have high heat capacities and cool treated areas as, or more rapidly than most alternatives such as gel packs or frozen peas (see below) (131). Treatments tend to last 10 to 20 minutes. Techniques are straightforward, but if ice packs are used, a slightly damp, thin towel is placed between the pack and the skin.

Iced whirlpools cool vigorously and usually are used for 10- to 20-minute periods. Although an athlete may be motivated to tolerate them, the average patient finds temperatures below 15°C uncomfortable. If the feet or hands are exposed to a cold bath, neoprene booties, hospital slippers, or woolen socks or gloves may increase tolerance.

Ice massage consists of rubbing a piece of ice (e.g., an ice cube or water frozen in a small cup) over the painful area. Analgesia can be achieved in 7 to 10 minutes, with most patients reporting successive sensations of cold, burning, aching, and numbness. A moisture barrier should be present between ice and skin, and ice should slide smoothly over the treated area. Although chemical and refrigerated agents may have tempera-

**FIGURE 63-8.** Ice is the mainstay of cryotherapy. Nevertheless, more sophisticated approaches are possible. This machine uses a chilled, inflated cuff to apply pressure and cooling to a knee injury.

tures below 0°C and can produce frostbite, ice treatments of healthy people for periods of less than 30 minutes do not seem to cause injury.

Vapocoolant and liquid nitrogen sprays can abruptly reduce skin temperature by 20°C (9) and are used for local skin analgesia and the “spray-and-stretch” techniques. Prepackaged chemical ice packs may consist of two compartments (e.g., one filled with water, the other with ammonium nitrate), which, when broken and the contents mixed, produce a cooling, endothermic reaction. Although these packs are convenient and pliable, they are small, expensive, and tend to cool poorly (131). Alternatives such as refrigerated and pressurized water pressure cuffs (Fig. 63-8) are also available. Twelve-ounce frozen orange juice containers and plastic bags of frozen peas, which conform to the body when struck on a hard surface, are effective alternatives for home use.

### Indications

#### Trauma

Many studies have found that chilling limits hypoxic damage, lessens edema, speeds recovery, and reduces compartmental pressures after injury (132). Although there are concerns that cooling does not reduce posttraumatic swelling, it does lessen metabolic activity and blood flow (126). It has been suggested that cooling may slow deterioration and improve neovascularization of surgical grafts (133).

Rest, ice, compression, and elevation (RICE) are the initial steps in treating many musculoskeletal injuries. For example, icing for 20 minutes per half hour to 30 minutes every 2 hours, for the first 6 to 24 hours, is a common ankle sprain regimen. Although ice is the mainstay of acute soft-tissue injury treatment, recent research indicates that the evidence supporting its use is more limited than previously thought (134). It is interesting that postsurgical studies of the knee (135), cesarean

section (136), and oral surgery (137) have reported limited benefit from the use of cryotherapy despite its widespread use.

After the first 48 to 72 hours, the choice between cryotherapy and heat is typically a matter of preference and experience. Some prefer heat and will use it unless there is a worsening of edema or pain. Others prefer cooling and believe that a combination of icing for 10 to 20 minutes to reduce pain, along with active exercising, is the most effective way to speed recovery. In any event, heat and cold are only adjuncts to a mobilization and exercise program.

### **Chronic Pain**

Patients with chronic musculoskeletal pain occasionally find ice extraordinarily effective. Here again, the results are mixed; while some investigators have found ice massage and transcutaneous electrical nerve stimulation (TENS) equally effective for chronic low back pain (138), a recent review found limited evidence of the effectiveness of cryotherapy in low back pain (139). Ultimately, patient tolerance will limit the applicability of ice therapy.

### **Spasticity**

Ten to twenty minutes of vigorous cooling reduces the tone of spastic muscle and may improve the isolation of voluntary function (128). Although cooling muscles before therapy might be helpful, its utility must be balanced against the time required. It is interesting that systemic cooling appears to reduce fatigue, improve balance, and increase strength in patients with multiple sclerosis who are “cryosensitive” (140). It may also produce a mild increase of spasticity (141).

### **Precautions and Contraindications**

The precautions shown in Table 63-4 should be heeded. Pressor responses aggravating cardiovascular disease should be considered, as should the effects of direct and consensual vasoconstriction on ischemic limbs and in people with Raynaud’s phenomenon. Cold hypersensitivity, urticaria, and even frostbite are possible. Patients with insensate areas and those who are unresponsive should not be treated with cryotherapy. Cryotherapy is uncomfortable, and it is important to explain its rationale before beginning treatment.

## **ULTRAVIOLET**

Ultraviolet (UV) radiation has a history of use as a therapeutic agent that began in ancient times in the form of helio (sun) therapy. It regained prominence in the early 20th century as a treatment of dermal tuberculosis (scrofula) and, although supplanted by more effective agents, was employed in the treatment of open wounds as recently as the 1980s.

The biomedical literature divides the UV spectrum into three parts: UV-A (0.315 to 0.4  $\mu\text{m}$ ), UV-B (0.29 to 0.315  $\mu\text{m}$ ), and UV-C (0.2 to 0.29  $\mu\text{m}$ ). UV-A penetrates most deeply but has the least biologic activity. UV-B produces sunburn and skin erythema. UV-C is bactericidal and also produces erythema.

## **Treatment**

Although the last 25 to 30 years have seen UV treatment almost disappear from the physical therapy clinic, it continues to be used in dermatology for the treatment of conditions such as psoriasis and atopic dermatitis (142). However, due to its past importance in therapy and its continued intermittent use, some discussion remains warranted.

UV exposure is limited by the nature of the tissue treated, source strength, and the separation of the tissue from the applicator. Exposures are quantified in terms of the time required to produce a minimal erythema (i.e., a minimal erythema dose [MED]). One MED (usually requiring 5 to 30 seconds with a cold quartz lamp) is established by exposing the volar forearm to a source and determining the time required to produce a minimal erythema several hours later. For reference, 2.5 MEDs cause reddening and pain that persist for a few days; 5 MEDs produce local edema, pain, and desquamation; and 10 MEDs result in blistering (143).

In general, UV treatments begin with 1 or 2 MEDs and are kept to less than 5 MEDs to avoid tissue damage (143). Open wounds are treated directly with a lamp. Specially designed orificial probes may be used for fistulas, undermined wounds, or the oral cavity.

UV-C was once a common skin ulcer treatment as its bactericidal effects (on motile bacteria but not spores) are well recognized (144). UV may also accelerate wound healing and wound margin vascularization (143,145), but alternatives such as occlusive dressings may be more effective (18), easier to use and less likely to produce side effects. It may be that the rise of antibiotic-resistant bacteria will provide a reason for increased use in the future.

## **ELECTROTHERAPY**

The ancient Greeks knew that amber rubbed with wool attracted light objects, and also electric eels, rays, and catfish could produce analgesia (146). This knowledge had little practical benefit until the rapid increase in the understanding of electricity and electromagnetism in the 18th and 19th centuries led to new search for healing effects. Early “medicinal” electricity applications were enthusiastic but haphazard. Electrostatic baths, spark treatments, and galvanically induced limb movement all had momentary popularity. Unfortunately, their utility was minimal and scientific interest waned until the last half of the 20th century (146).

Today, high-intensity electrical stimulation is used to strengthen muscles and to move paralyzed limbs. Less intense stimulation produces analgesia and delivers medications percutaneously. Stimulation at still lower intensities has gained FDA approval for fracture healing. Soft-tissue wounds, osteoporosis, and musculoskeletal pain represent additional potentially important but still investigational electrical stimulation applications. This section discusses these agents.

### Transcutaneous Electrical Nerve Stimulation

The gate theory of pain postulated in 1965 that cells in the spinal cord substantia gelatinosa serve as gates to pain perception by inhibiting the passage of nociceptive information to the brain if sensory afferent signals are present (147). TENS provided sensory afferent signals and, after some successful trials, became widely accepted.

The mechanism of action of TENS remains controversial. Although research shows that stimulation reduces dorsal horn cell activity (148), the gate theory does not explain phenomena such as painless sensory neuropathy, analgesia persisting after stimulation, and delayed onset of analgesia. As a result, other explanations, such as those involving frequency-dependent effects and central nervous system endorphins, have been advanced by a number of investigators (149).

TENS units consist of a battery, one or more signal generators, and a set of electrodes. Units are small, usually programmable, and generate a variety of stimuli with currents of less than 100 mA, pulse rates ranging from a few to 200 Hz, and pulse widths of from ten to a few hundred microseconds. Asymmetric, biphasic waveforms are favored to improve comfort and to avoid the electrolytic and iontophoretic effects associated with unidirectional currents. Additional features such as “burst” modes and wave-train modulation are common but of unclear benefit.

Electrode positioning is more art than science. Placement over the painful area is usually the first choice, but locations over afferent nerves, nerve roots, acupuncture and trigger points, and auricular sites, as well as contralateral to the pain, are also possible. Although carbon-impregnated rubber electrodes are inexpensive, more expensive self-adhesive electrodes are far more convenient.

Stimulus parameter choice is also subjective. Many prefer to begin with low-amplitude, 40- to 80-Hz “conventional” settings and use the less comfortable high-intensity, 4- to 8-Hz alternative if the first trials are unsuccessful. Ideally, initial benefit is established in a few therapy sessions and an overnight trial. If TENS appears effective, the patient should rent an identical unit for a month or more. Response is difficult to predict, and parameter selection is ultimately based on trial and error. TENS units vary in price depending on their source and complexity. Some can be quite expensive and as benefits often wane with time, purchase should be considered only if benefits persist for at least a few months.

### Indications

TENS studies range in quality from well-designed, prospective, randomized controlled trials to case reports. Success rates vary from placebo levels to 95% and may be affected by the choice of stimulating parameters, electrode placement, condition treated, chronicity, and length of follow-up. Even when studies are controlled, it is not clear whether the controls should be sham TENS or an alternative treatment.

A number of studies in the 1970s and 1980s found that TENS lessened postoperative and early labor pain, decreased narcotic use, and shortened intensive care unit stays. These

studies also tended to find TENS-induced pain relief equivalent to that achieved by the consumption of limited amounts of analgesics/narcotics and that success rates decreased as the duration of follow-up increased.

### Acute Pain

Surgical pain is a convenient model for acute pain, and a number of more recent studies have found benefits in TENS use. Benefits are not universally found and be limited to a specific condition (150). Parameter choice appears important. Thus, two RCTs that used peri-incisional either low frequency (2 Hz), high frequency 100 Hz, or a combination of the two in large groups of women having gynecologic surgery found that TENS resulted in a 30% to 50% reduction in the use of analgesics with the 2- to 100-Hz combination appearing the most beneficial (150–152).

### Musculoskeletal Pain

While the earlier reports were relatively encouraging, more recent research may put a harsher light on TENS benefits. For example, a 2001 evidence-based clinical practice guidelines panel concluded that TENS did not lessen acute or chronic low back pain (153,154). Similarly, a 2005 review of treatments for acute neck pain found insufficient evidence of any benefit (155). Findings for subacute low back pain may be more positive but are still equivocal (156).

It is intriguing that while the evidence of TENS effectiveness in spinal pain seems so limited, a stronger case appears possible for its use in osteoarthritis. For example, several reviews and panels find that TENS is beneficial in the treatment of osteoarthritis (particularly of the knee). There is also evidence that benefits require treatments of 40 minutes or more duration (157).

In summary, while some patients may use TENS for years at a time, support for its use remains mixed and may depend in ways we do not understand on factors such as chronicity, parameter choice (158), and the condition (159). For example, a frequent conclusion of even large systematic reviews is that while the majority of studies may find benefit, the power and quality of the trials are too low to permit a definitive determination. In the case of rheumatoid arthritis, for example, a 2004 review found evidence of effectiveness of TENS for pain relief (80), although these benefits may not be as clear for treatment of the hand (160).

### Urologic and Gynecologic Issues

While musculoskeletal pain is the main focus for many TENS applications, a significant amount of attention has also been placed on other conditions such as gynecological pain. The findings are again mixed. For example, a meta-analysis of nine RCTs found support for the use of TENS in the treatment of dysmenorrhea (161), while another systematic review of eight reports involving more than 700 women found only weak support for the use of TENS during labor (162). Interestingly, an RCT crossover trial of 43 patients with detrusor instability found 20-Hz perianal TENS was as effective as 5 mg of

oxybutynin three times a day in reducing the symptoms of urinary urgency (163). In a similar vein, a review of evidence in this area highlighted the potential role of TENS in childhood detrusor instability (164).

### Other New and Potential Applications

#### *Traumatic Brain Injury*

Data in this area are sparse but may grow with time to support or dispute a few intriguing preliminary findings in this area. Dorsal column stimulators (DCS) have occasionally been used in an attempt to hasten the arousal of patients with severe traumatic brain injury. Investigators have begun extending the concept to stimulation of the median nerve with 40-Hz TENS on the theory that this approach is less invasive and the median nerve has a large cortical representation (165). However, effectiveness is not established, much less a comparison with an alternative treatment such as methylphenidate is limited. TENS has also been promoted as an effective noninvasive method of pain relief in patients with traumatic brain injury (166).

#### *Angina*

Many consider precordial TENS use contraindicated. However, TENS may reduce cardiac ischemia, perhaps by lessening sympathetic tone, and increase cardiac blood flow (167). In addition, TENS may lessen the number and duration of silent ischemic attacks, although its effect on the total number of attacks (silent and painful) may not be significant (168). Given the concerns about the risk of this approach, more research in monitored settings seems necessary despite the fact that a number of reviews have highlighted the potential role of TENS as an alternative to pharmacological management of the pain and symptoms of angina (169,170).

#### *Blood Perfusion*

The effect of TENS on cutaneous blood flow or temperatures in normal subjects is controversial (171,172). However, some evidence suggests that it may improve cutaneous perfusion, increase distal skin temperatures, and lessen pain in people with scleroderma and diabetic neuropathy (173).

#### *Spasticity*

Spasticity reduction following TENS use has been reported for patients with stroke, spinal cord injury, and multiple sclerosis (174). Effects are controversial, but a recent review of treatments for spasticity following spinal cord injury identified TENS as the only nonpharmacological intervention supported by high-quality evidence of effectiveness (175).

Only a limited proportion of patients who try TENS benefit (176). Some clinicians feel that fewer than half the patients with chronic musculoskeletal conditions find TENS helpful initially and that benefits persist more than a month in fewer than half of these. Studies of long-term users find that about 75% of individuals who have purchased a unit may be still using it after 6 months to a year (177,178), but use may continue to decline to about 30% at 3 years (179). The best

results in these chronic users seem to occur in musculoskeletal pain, neurogenic pain, and angina. People with psychogenic pain, central pain, autonomic dysfunction, and social distress may respond less well (179).

### *Precautions and Contraindications*

TENS has few safety issues other than contact dermatitis and skin irritation, which usually respond to changes in electrode type and placement. High current densities, either due to the setting of the unit or to a partially detached electrode, are uncomfortable but are easily corrected. Cardiac pacemakers seem resistant to TENS, but, as noted above, concern about the possibility of ectopically generated rhythms seems to dictate avoidance over the pericardial area or in patients with pacemakers, electrical implants, and dysrhythmias. Treatment near the carotid sinus and epiglottis and over the low backs, abdomens, and lower extremities of pregnant women should be avoided. Psychogenic pain is particularly resistant to TENS, and use in this setting should be judicious. The preceding precautions may err on the side of caution as there is little documentation to support their validity.

### **Iontophoresis**

Iontophoresis uses electrical fields to force electrically charged or polarized ions and molecules into tissue. Speed of movement is related to voltage and field strength, whereas the amount of material introduced into the tissue is proportional to the current. Penetration is dependent on a substance's size and polarity and may be particularly intense at sweat glands and areas of skin breakdown (180). It may not always be necessary to have an "active ingredient." Iontophoresis with tap water at current intensities of 10 A/cm<sup>2</sup> may increase local skin temperatures by 1°C and microcirculation severalfold (181).

An iontophoretic unit is simple and may be contained within a disposable skin patch. In general, it consists of a direct-current power source, two electrodes, and a pad moistened with a dilute (often 1%) solution of the desired (charged or polar) substance placed under the electrode of the same polarity. Currents are determined by multiplying the area of the active electrode by 0.1 to 0.5 mA/cm<sup>2</sup>. The size of the inactive electrode is immaterial but is kept as large as convenient for patient comfort. Electroporation uses brief periods of high voltages to increase cell membrane permeability in gene and cell studies. Its potential application to iontophoresis seems possible.

### **Indications**

Tap water iontophoresis is reported to produce benefits of 4 to 5 weeks or more in 90% of patients with hyperhidrosis (180,182). The treatment approach varies with the location treated. In the case of the distal limbs, the hands or feet may be placed in a container with both the anode and cathode or with one extremity and one electrode in each of two containers. Currents vary with the approach but are often 10 to 30 mA. The mechanism of action is unclear but may result from the preferential flow of ions along the sweat ducts.

Sodium fluoride iontophoresis is reported to reduce tooth hypersensitivity (183). Iontophoresis has also been found to improve delivery of a variety of antibiotics such as gentamicin, penicillin, and cefoxitin into the poorly vascularized tissues such as the eye and burns and cartilage (184,185).

Iontophoretic treatment of postherpetic neuralgia with methylprednisolone and lidocaine as well as Achilles tendonitis with dexamethasone has been reported to produce prolonged benefits (186,187). A recent RCT found iontophoresis to provide equivalent short-term benefits to injection of corticosteroids for carpal tunnel syndrome; however, the latter provided superior effect in the longer term (188). In contrast, RCTs of steroidal iontophoresis in the treatment of plantar fasciitis and lateral epicondylitis as well as acetic acid in shoulder tendonitis found minimal to no benefits over conventional therapy or placebo (189–191).

### Safety

Iontophoresis is a safe therapy. Complications occur but tend to involve allergic reactions or to be similar to those of TENS.

### Electric and Low-Intensity Electromagnetic Fields

Bone and soft-tissue injuries produce electrical fields and currents that can alter cell orientation, proliferation, calcium concentrations, and motility (192). These fields have very low intensities (approximately 1 V/m rather than the 70,000 V/m [70 mV/m] associated with cell membrane potentials), and their mechanism of action may include a switch effect that alters cell permeability.

### Wound Healing

Interest in electrically stimulated wound healing extends back to at least the early 1970s with reports that low-intensity direct current accelerated the healing of ischemic wounds (193). These early studies were marred by poor design, and while the approach was not widely accepted, the interest never disappeared. Today, protocols often similar to the earlier studies use low-frequency (10 to 200 Hz) and low-intensity ( $10 \mu\text{A}/\text{cm}^2$ ) electric currents and electromagnetic fields to speed the healing of soft-tissue wounds. Benefits remain difficult to establish, but there is some experimental support for the approach, and the well-accepted benefits of electrical stimulation on nonhealing bony fractures (194) has only served to maintain interest.

Wound studies are notoriously difficult to carry out, and unfortunately, this has proved true for those assessing the benefits of electrical stimulation. Thus, while TENS stimulation has been reported to improve healing and elevate distal limb temperatures in patients with diabetic neuropathy and scleroderma (195), the studies are usually limited by sample size and may or may not show stimulation accelerates healing. In fact, two recently updated Cochrane reviews concluded that the database was too limited to permit an assessment of benefits of electrical stimulation in the healing of either venous or pressure ulcers (196,197).

### Musculoskeletal Pain

Musculoskeletal pain has proven to be a focus of electrotherapeutic research with a particular emphasis on pulsed EMF (PEMF). The results are again intriguing but less than convincing. For example, while controlled studies have reported that low-intensity pulsed shortwave diathermy (27.12 MHz,  $1.5 \text{ mW}/\text{cm}^2$ ) produced clinically and statistically significant improvements in neck pain or ankle sprain (198,199), a more recent investigation involving patients with subacromial impingement failed to find benefit from the addition of PEMF to their rehabilitation program (200). Reviews provide a similarly mixed picture. Again, sample size is an issue. Thus, while a 2002 Cochrane review that encompassed only three studies determined that electromagnetic fields were more effective than placebo in the treatment of osteoarthritis (201), a more recent 2006 review focusing on osteoarthritis of the knee that included five RCTs found no convincing evidence of benefit (202). Ultimately, acceptance of electrical and electromagnetic stimulation as a treatment option will depend on cost, comfort, convenience, and evidence of effectiveness.

### Interferential Current

TENS units and muscle simulators are limited at times by the discomfort that strong stimulation at low (e.g., <80 Hz) frequencies produces in the skin. However, skin impedance decreases with frequency, and higher frequency waves can penetrate to deeper tissues without discomfort. Interferential current (IFC) devices (Fig. 63-9) take advantage of this fact by having two high-frequency (e.g., 2,000 to 4,000 Hz) sine waves differing by 20 to 100 Hz overlap each other in tissue. Beat frequencies equal to the sum and differences of the sine waves are produced with the difference in frequency within the therapeutic 20- to 80-Hz range.

**FIGURE 63-9.** IFC treatment. This treatment uses the interference pattern of two higher frequency sine waves to apply electrical stimulation. Although only three electrodes can be seen in the picture, four are required (two for each wave train).

IFC appears useful (particularly in a sweep or vector mode) when TENS effects are desired. Despite this, there is no clear demonstration of its superiority over other devices: for example, a recent trial on treatment of dysmenorrhea found no difference in the effectiveness of interferential or TENS stimulation (203). Evidence to date for musculoskeletal pain management has been mixed with positive (204,205) and negative findings (206) reported. Interestingly, studies using experimental models of pain in humans have consistently failed to show any significant effect with the use of interferential therapy (207–209).

### Safety

These devices operate at low powers and are used for limited periods. Although there has been a report of a burn arising from treatment with IFC following knee arthroplasty (210), the devices appear safe, and the precautions necessary seem to be those outlined for TENS and electrical devices in general.

Epidemiologic studies have at times associated prolonged exposure to low-intensity EMFs (such as those associated with power lines, hair dryers, and cell phones) with increased rates of leukemia, miscarriage, and brain tumors (Table 63-5). These studies are of concern, but all have methodological shortcomings. A number of panels, including a 1996 National Research Council review panel, have met over the years and concluded that while extremely low-frequency (ELF) magnetic fields 0.4T may be associated with increased rates of childhood leukemia, neither static magnetic fields nor ELF electric fields pose any known risk (211,212). This question has gained new importance with the advent of cell phones but at this point, risks seem minimal and, if present, subtle.

## Alternative Therapies

### Vibration

Vibration and tapping have had a long-term role in neuromuscular rehabilitation as a way to facilitate muscle recruitment (213). Traditionally, vibration was applied to a limited number of limb muscles with a handheld applicator. Research is limited but many clinicians believed that frequencies of about 150 Hz and amplitudes of 1.5 mm were particularly effective (213, 214) and might have some analgesic (215) or wound-healing effects (216).

Vibration, however, has recently been regaining attention. Much of this interest appears based on clinically observable improvements in recruitment that localized vibration produces in the muscles of patients with neurological conditions such as stroke and Parkinson's disease. Gait and balance form a particularly strong area of investigation. In these cases, the whole body is typically vibrated with the patients standing on a platform while their body is subjected to small amplitude rhythmic displacements. Initial results in terms of improvement mobility and balance are mixed and require further assessment (217).

### Light and Laser Therapy

Low-power lasers (and monochromatic light sources) have been used since the late 1960s to lessen the pain and speed

**FIGURE 63-10.** Laser therapy. In this case, a handheld 30-mW IR diode laser is being used to treat an ankle sprain. This therapy is available in many parts of the world and has recently gained FDA approval for a limited number of indications.

the healing of a variety of neuropathic, inflammatory, and soft-tissue conditions. Initially, treatment involved short exposures to a variety of  $\leq 1$ - to 5-mW lasers. With time, therapy practices have coalesced, and now, most treatments are performed with 30- to 150-mW IR diode lasers (Fig. 63-10). Although treatments do not elevate tissue temperatures more than a few tenths of a degree, laboratory studies find irradiation stimulates collagen production, alters DNA synthesis, and may improve the function of damaged neurological tissue. Extension of these effects to humans has been more difficult.

Laser therapy received its first impetus in the 1960s from claims about its ability to heal chronic, nonhealing wounds (218). This claim has been surprisingly difficult to substantiate. Thus, while the underlying mechanisms have been well researched at cellular level, support for benefits has been progressively more difficult to establish at the animal and human levels. However, at least one well-controlled study of superficial wound healing found benefit of laser irradiation (219).

Use of this approach lagged in the United States due to the previous lack of FDA approval (220). The FDA reduced its requirements in 2002 to that of a single positive clinical study and has subsequently approved more than 25 devices for adjunctive use in the treatment of pain.

As is true for many modalities, confirmation of benefit is conflicting and confusing. Thus, several systematic reviews have provided evidence of effectiveness of these devices in the short-term alleviation of joint pain (221), knee osteoarthritis (222), and temporomandibular joint pain (223). Surprisingly, these benefits do not seem to extend to neck pain (224) or lateral epicondylitis (225) and in the shoulder may be limited to adhesive capsulitis (226). Similarly, while several trials have indicated potential benefits in the treatment of fibromyalgia (227) as well as part of a program for the management of chronic low back pain (228), a 2007 review of treatments

for carpal tunnel syndrome found conflicting evidence for laser therapy (229).

Static Electric and Magnetic Fields

The potential health benefits of electric and magnetic fields have intrigued humans for thousands of years. Interest has fluctuated with time, but the magnetic devices advertised today differ little, other than in complexity, from the magnetic rings of the Greeks and therapies of 150 years ago.

There is support for the idea that these fields might have clinical utility. For example, low-intensity static and dynamic magnetic fields may alter balance, learning, pain perception, behavior, and anxiety (230,231). Again, however, findings are mixed, and other studies may fail to find these effects (232,233).

Indications

Unfortunately, although there are a number of alluring reports, objective clinical support in either the human or the veterinary literature is limited. Thus, although a study may find magnetic fields beneficial in conditions such as postpolio pain, peripheral neuropathy, rheumatoid arthritis, and neck and shoulder pain (234,235), others may find no effect (236,237).

Safety

Safety does not seem to be a particular issue. As noted earlier, a number of panels have concluded that neither static electric nor magnetic fields pose any known risk (211,212). As a point of reference, the FDA has classified static magnetic fields of less than 4T as nonsignificant risks for research subjects (238). Even hour-long exposures to 8-T field strengths, although they do produce temporary changes in ECG readings, do not alter heart or respiratory rates, blood pressure, cardiac output, or body temperature (239).

Extracorporeal Shock Wave Therapy

Although extracorporeal shock wave therapy (ESWT) has gained prominence over the last 15 years as a potential treatment of a variety of soft-tissue disorders (58), its potential for plantar fasciitis and calcific tendonitis seems particularly promising. A number of controlled studies have found ESWT effective in the treatment of calcaneal bone spurs (240) and calcific tendonitis of the shoulder (241–243), although results for lateral epicondylitis appear more equivocal (244,245). Better targeting of the treatment area as well as higher levels of stimulation may produce better results than generalized or low-intensity treatment, but whether ESWT has any unique benefits or is merely a new way to apply controlled trauma to reinitiate healing is yet to be established.

MODALITY CHOICE AND PRESCRIPTION

The physical agents are typically prescribed as part of a program that may also include massage, exercise, and education (Table 63-7). As this table shows, a well-written prescription

TABLE 63.7 Elements of a Physical Therapy Prescription

Patient
Diagnosis
Modality
Treatment area
Treatment parameters (intensity, power, frequency, duty cycle)
Frequency and duration
Additional treatments (e.g., massage)
Exercise
Patient education
Recheck schedule
Treatment goals

involves the same elements that are common to all good writing: who (the patient), what (the agent), why (the diagnosis), where (the treatment area), when (the frequency and duration), and how (intensity, device settings).

Modality choice depends on balancing of the diagnosis, the characteristics of the agents, evidence of effectiveness, concurrent issues (e.g., level of cooperation, anticoagulation, preference), and treatment goals. General rules introduce some order into the situation. For example, acute (<24 to 48 hours) musculoskeletal conditions are usually treated with cooling. Hot packs, cool packs, hydrotherapy, shortwave diathermy, and some of the electrical therapies are commonly used to treat broader areas. More intense agents such as ice massage and ultrasound are more common if smaller regions are to be treated. The diathermies are frequently favored for deeper tissues, but the comfort-inducing effects of superficial agents may be as beneficial. In the end, choice involves blending a physiologic understanding of the agents, experience, preference, and equipment availability. As research continues, our knowledge will grow. Choices common today will undoubtedly appear quaint in the future.

# Manipulation, Massage, and Traction

Manipulation, massage, and traction have been used in various forms for several thousand years throughout the world. Each includes treatments for the relief of painful conditions—sometimes with noticeable immediate effects—that are sought by an ever-increasing number of people; as an example, manual medicine procedures, including manipulation, are very much in demand by patients, of whom a reported 12 to 17 million Americans alone, who seek, receive (over 90 million manipulations alone) and are very satisfied with them on an annual basis (1,2). Despite consistent high demand for these treatments, evidence of the effectiveness of some of the techniques comprising them has been difficult to obtain and complete acceptance within the medical community has, to date, been mixed.

Some argue that patients who improve and report feeling better with these treatments may have done so anyway and that serious complications (which are rare and usually due to either an unqualified practitioner or the performance of an inappropriate maneuver) sometimes occur; that treatments are aimed at the pocketbook and not the pain; and that claims of success are sometimes unproven (3). The Agency for Health Care Policy Research (AHCPR) (4) recommendations that include manipulation, for example, as an option in acute low back pain management have done little to resolve these differences (5).

What has led to this apparently dichotomous thinking? One factor may be that some traction, manipulation, and massage techniques have an as yet uncertain mechanism of action. In addition, they are treatments that can be performed by nonphysicians. A treatment appears less scientific and perhaps less efficacious if it can be obtained from nonphysician, even nonlicensed, practitioners. A more acceptable rationale for rejecting these treatments may be the paucity of scientific proof of benefit.

The use of any treatment should be limited to those conditions that can reasonably be expected to improve with the physiologic effects of that treatment. The macroscopic effects of traction and massage have been partially elucidated and offer some degree of guidance regarding indications. This is not yet the case for manipulation, although evidence is growing. In the remainder of this chapter we will discuss what information is available regarding the use and efficacy of these treatments and attempt to provide the physiatrist with a basis for understanding their use and role in the treatment paradigm.

## MANIPULATION

### Introduction

Although manipulation has been widely practiced in almost all countries of the world since at least the time of Hippocrates (6), the subject often evokes strong emotional responses among health care professionals, particularly in the United States and Great Britain. Since the 1890s, when manipulation became a cornerstone of the therapeutic approach of the Osteopathic and Chiropractic Schools of Medicine, the subject has caused debate among practitioners.

Manual treatments are among the most common procedures utilized on a daily basis across the globe; they are performed by physicians, physical therapists, chiropractors, nurses, athletic trainers, naturopaths, massage therapists, lay practitioners, and others. Early references to manual medicine can be found in the writings of Hippocrates, as mentioned above, and in ancient Egyptian hieroglyphics and early Chinese medical literature (7). In the United States, the roots of manual medicine can be traced to Andrew Taylor Still, M.D., and his contemporary, Daniel David Palmer. The former started his American School of Osteopathy in Kirksville, Missouri, in 1892, the latter opened the first chiropractic college in Iowa in 1895 (8). Today, manipulative treatments continue to be developed and researched nationally and internationally by an ever-growing cadre of practitioners.

This section provides a brief review of manipulation, describes some of the forms of treatment, and discusses the use of manipulation and its prescription, with a focus on physiatry, and physiatric application of manual medicine. The techniques described will be neither osteopathic, nor chiropractic, *per se*, but rather a combination of terminology and treatments a physiatrist is most likely to encounter.

The purpose of this section is to introduce manipulation and discuss its applicability to physiatry and to present some general guidelines for appropriate prescription. The evidence base for these treatments will be referenced where applicable and available, but we will neither attempt to settle ongoing disputes concerning the efficacy of manipulation nor comprehensively cover all forms of manual treatment or diagnosis.

### Definition

The definition of manipulation is controversial, but a consensus definition is that it is “the use of the hands in a patient’s management process using instructions and maneuvers to achieve

maximal painless movement of the musculoskeletal system and postural balance” (8). More specifically, spinal manipulation is a mechanical treatment applied to a specific vertebra or vertebral region, including the sacroiliac region and the rib cage, by a physician or therapist with the primary goal of restoration of lost vertebral motion. Nonthrust techniques (“mobilization” to a physical therapist) are encompassed by this narrower definition. Active exercise, self-applied forces, or self-induced motion, although occasionally effective in the restoration of vertebral mobility, are not included. Massage, which is applied only to soft tissue, and traction, which is nonspecific to a vertebral region, are excluded by this definition, although the reader will recognize that some overlap among manipulation, traction, and massage occurs. The interested reader will find a detailed history of manipulation in a number of sources (6,9,10).

While the majority of manipulative treatments performed in the United States are aimed at the cervical and lumbosacral regions to treat musculoskeletal symptoms, manipulation can be performed on any part or region of the body. It is generally directed at restoration of normal motion and elimination of pain secondary to disturbed biomechanics. It is an application of forces to the muscles, tendons, ligaments, joints and capsules, bones and cartilage of the vertebral column, or other tissues, with a primary aim to restore the body to a state of homeostasis (11). Although often taught in a regimented way, the application of manual treatment should not be formulaic or protocol driven, but, rather, customized to the individual patient and based on a careful and thorough history and physical examination. Assessment involves the examination of the restriction of motion and the asymmetry of the joints in a given area of the body, as well as that in contiguous and adjoining regions. Generally, one tests for areas of tissue texture changes, pain in or sensitivity of the area, or a change in the quality of motion within a body region.

From a biomechanical perspective, an area of structural hypermobility or hypomobility, such as in adjacent vertebrae or other skeletal or muscular structures, is most often a consequence of a problem elsewhere in the body. When a certain degree of motion is expected in one area and it is deficient, another region then typically compensates for this with its usual motion, plus at least a few degrees more. If, for example, a stroke patient with hemiplegia presents with low back pain, one can treat the restrictions and dysfunction found in the lumbar spine and, if present, in the pelvis as well. These treatments may give the patient substantial relief of lumbar pain, but the pain and dysfunction will soon return if there is an overlooked causative restriction elsewhere. Consider, as an example, the patient’s lower limb weakness; the altered mechanics of the patient’s gait alone will affect both sides and compromise both pelvic and lumbar motion. Manipulation alone would be inappropriate as the neurologic deficit is not amenable to this form of treatment. Using manipulation to treat the dysfunction of the lumbar spine and other areas, in combination with physical therapy, assistive devices, and other appropriate physiatric care, may optimize this patient’s functional recovery and lessen the severity of the low back and pelvic symptoms.

The majority of the studies and review articles pertaining to manipulation have focused on the application of these treatments to the cervical and lumbar spine and on the use of thrusting techniques in particular. It is important to realize that there are many other types of manipulative techniques and which one is chosen should be based on a thorough examination of the patient and the musculoskeletal lesion to be treated. It is essential to find the cause of the illness or dysfunction if the most efficacious treatment or combination of treatments is to be chosen and applied.

## Techniques of Manipulative Treatment

In the following introductions to the most common techniques of manipulation used in the United States, discussion is limited to those that the physiatrist is most likely to encounter early in the investigation of manipulative care.

The concept of direct and indirect treatment is ubiquitous in the literature regarding manipulative technique. As previously mentioned, an accurate and thorough examination and localization of musculoskeletal dysfunction are essential. Before initiating treatment, any restriction in range of motion, either gross or subtle, should be detected during passive motion testing. This restriction is commonly termed a *barrier* (this is fully explained below). Direct treatments engage the barrier and focus mechanical forces into the motion restriction to eliminate it. In contrast, indirect treatments avoid the barrier and instead focus treatment within the joint range that allows the most fluid motion in order to expand normal range by neuroreflexive means.

## Thrust Techniques

Other terms for thrust techniques (9,10) include impulse, which is of European origin (9), high velocity/low amplitude, adjustment, and spinal manipulative therapy (SMT), which are of chiropractic origin. In most approaches, the operator diagnoses the dysfunctional vertebral segment by identification of position or motion abnormalities or by related tissue changes, including tenderness to palpation or induced motion. He or she then rotates, side-bends, and flexes or extends the vertebral segments below it, thereby engaging or “locking” the facet joints so that further motion is limited to the vertebra in question. This vertebra is then passively moved to its limit of motion (i.e., its barrier) to remove all slack motion. A small force localized to the joint in question and in the direction of the restricted motion is applied to hold this position. Finally, a brief (9,10,12) controlled thrust is applied to the involved vertebra in the restricted direction, and a small motion, flexion, extension, rotation, or side bending, occurs as the vertebra traverses the barrier (Fig. 64-1). Often an audible “pop” or “click” is produced. The source of this sound has been attributed to cavitation (13) and nitrogen release in the synovial facet joint. Its presence infers that a mechanical process has occurred over a much shorter time than for inaudible events, such as reflex muscle contraction. This further suggests that audible thrusting procedures have a different mechanism of action and possibly different level of efficacy compared with

**FIGURE 64-1.** In the thrust technique, the patient is relaxed and is not applying force ( $F_p$ ). The manipulator applies a quick force ( $F_m$ ) in the direction shown, to extend the upper vertebrae to the anatomic limit in one motion. In the muscle energy technique, the manipulator applies force ( $F_m$ ), and the patient contracts muscles with net force ( $F_p$ ) in the directions shown, so that no torque exists around the center of flexion-extension rotation. After 5 seconds, the patient and doctor relax, and a new extension barrier to passive range of motion nearer to the anatomic limit is found. Repeated manipulations will bring succeeding barriers closer to the normal passive anatomic limit.

other manipulative procedures. It is arguable whether there is clinical relevance to this sound (9,10,11). All thrust techniques can potentially do harm if forces are not well localized and/or misdirected along axes which do not correspond to correction of the dysfunctional segment at the vertebra or vertebral region involved. Again, precision of localization and placing the joint or segment into its restrictive motion barrier so that the physician has maximal control of force applied and uses only the force sufficient to create or restore motion is desired to thereby complete the treatment (14). Ideally, one should use the minimal force over the shortest distance possible to achieve the desired results.

### Articulatory Technique

The articulatory technique (9,10,15), also referred to as mobilization in Europe and *low velocity/high amplitude* in the United States, is very similar to oscillatory (16) techniques performed in Australia. The vertebral joint is passively moved within the reduced range defined by its resting position and the dysfunctional limit of motion. The extent of motion and its endpoint are varied, but ultimately the endpoint and dysfunctional barrier become the same, and the barrier is teased with repeated motion. Ideally, the quality or feel of the induced motion and the quantity of force and excursion are normalized by this procedure. Occasionally, a small amount of additional force takes the vertebra through its barrier or restriction, and this technique may then appear like a thrust. Other variables include frequency of repetition, duration of “hold time” at the extremes, and the rate, rhythm, and amplitude of oscillation (depending on underlying tissue texture) (16).

### Positional Techniques

The underlying principle in counterstrain and functional technique is that hypomobility is caused by an inappropriately firing muscle, that is, active tissue, rather than a shortened passive tissue such as capsule, myofascial, or ligament.

Thrust, articulation, and muscle energy techniques all employ forces that might be expected to lengthen shortened passive tissues, whereas the positional techniques attempt to change an inappropriate engram, or central pattern, of vertebral muscle behavior, similar to what is done in rehabilitation of head injury and tendon transplants.

### Counterstrain

Counterstrain (9,16,17) is an indirect myofascial technique developed by Jones (18) that shares with functional technique (discussed later) the emphasis on relative positioning of a joint or body part as an essential component of the treatment. This technique involves placing the joint or body part into its position of maximal “ease” or comfort, relaxing myofascial or ligamentous soft tissues. This allows inappropriately shortened muscles to “reset” their spindles, which then are thought to normalize their proprioceptive input to the spinal cord. Generally, the restricting muscle is overly shortened by this positioning (counterstrain), and its antagonist muscle is gently overstretched (strained) in the process. The treatment position is found by palpatory pressure and minimizing the pain at an associated counterstrain “tender point” to less than 80% of its initial degree of tenderness (15,17,19). This position is then maintained and held for 90 seconds for vertebra and other points, except for ribs which are held for 120 seconds (19). On occasion, small “fine-tuning” passive repositioning movements with feedback from the patient may be needed. Because tenderness is a part of this feedback system, the patient must respond to the questions of the practitioner regarding their degree of pain or “tenderness” at the noted point(s). The patient is then slowly returned to the neutral position, usually in one plane of motion at a time, to prevent resumption of the inappropriate muscle firing. Structural reassessment is then repeated.

The tender points of counterstrain do not coincide with the trigger points of Travell (252) or the similarly named tender points associated with fibromyalgia. Those of

counterstrain are usually small, discrete, fibrotic areas thought to be manifestations of distant arthrodial or myofascial restriction (9); they are not paired but may be associated with the other features of fibromyalgia such as stiffness, fatigue, and sleep disorders. They are distributed throughout the body in reproducible locations depending on the nature and location of the associated biomechanical dysfunctions. They are similar to those found in fibromyalgia in that they cause local pain when palpated rather than in a distant referral pattern. Counterstrain is considered to be gentle, safe, effective, and atraumatic; because of this, it is considered to be useful in elderly and hospitalized patients, in children, and in patients with fear of pain. This technique is easy to perform and relatively forgiving. It is easily incorporated into a home exercise program as well.

### Functional Techniques

Functional techniques (9,12,20), developed in the 1940s and 1950s, share with counterstrain a methodology oriented to reducing inappropriate afferent impulses from nociceptors and mechanoreceptors (and the resultant efferent  $\alpha$  motor activity to the skeletal muscle) by placing the joint or body part into a position of maximum ease (11). Unlike counterstrain, the position is found and monitored by the practitioner sensing increased tissue tension to small, induced motions. The patient provides “respiratory assistance” as he/she inhales and exhales to varying degrees to facilitate the release of the involved soft tissues.

Practitioners feel that passive positioning to maximum ease allows the firing pattern of the aberrant muscles to reset such that they are normalized in a neutral position. This approach, unlike counterstrain, does not make use of tender points and is, in principle, more objective because only the practitioner’s palpation determines the positions of balance. Functional techniques (nontraumatic and repeatable) are useful in both acute and chronic conditions.

### Muscle Energy

This nonthrusting technique (9,10,21,22) is also called isometrics and, by some Europeans, like articulatory technique, mobilization. Similar to proprioceptive neuromuscular facilitation (PNF), it uses stretch reflexes and isometric contractions to relax the target muscle (23–25). The muscle energy technique requires the operator to position the patient into the motion restriction barrier and take up slack as in direct thrust techniques. Instead of an impulse against the restriction, however, the practitioner instructs the patient to exert a small isometric force away from the barrier. Simultaneously, the practitioner provides equal resistance, preventing active motion. The patient holds the isometric contraction 5 to 10 seconds. After the patient relaxes, the affected joint can passively move further beyond the original restriction to a new barrier. The contract-relax effort is often repeated several times, engaging successive barriers with sequentially improved motion.

### Soft-Tissue Techniques

The soft-tissue approach uses mechanical stretch of the skin, muscle, and fascia to increase their motion. Lateral stretch (or “bow-stringing”), linear stretch, and deep inhibitory pressure are the most common procedures. This approach is useful in virtually all patients, often as a first step in treatment involving multiple manipulative approaches. Encouraging overall circulation and enhancing venous and lymphatic flow are central to these techniques (9). The overall purpose of soft-tissue technique is to relieve superficial muscle and fascial tension.

### Myofascial Release

The myofascial release approach (9,26–28) to manipulation overlaps somewhat with massage and, conceivably, with traction. It can be directed at hypomobility of a vertebra, of a vertebral segment (as in spinal manipulation), or of the entire body, in which case it resembles some massage techniques. It can be indirect, whereby a restricted area is placed into a position of little resistance until relaxation occurs, or direct, in which case the affected area is placed against the restriction barrier with constant force until a fascial release occurs. Conceptually, in this approach, all the myofascia in the body are interconnected, and when one area is tight or restricted, diminished movement results locally and in more distant areas.

Practitioners continually palpate to assess tissue response and adjust the applied forces of stretch, traction, pressure, or twist they are using, until the affected tissues are felt to change, often called a “release.” The actual forces are combinations of those used in massage, soft tissue, muscle energy, and possibly craniosacral techniques. The mechanism of the release of the “tightness” can be biomechanical (such as viscoelastic strain) or neuroreflexive, but, when accomplished, fascial resistance to forces applied should be symmetric, and the tissues should be relatively mobile, that is, responsive to the force.

### Joint Play

This concept addresses the immediate cause of the joint motion restriction. In an idealized joint, the bone moves in small precise ranges, independent of voluntary muscle contraction, over the stationary contours of opposing joint surfaces as motion in the voluntary direction occurs. But actual joints sometimes have noncongruent and sometimes diseased nonsmooth surfaces, resulting in movement in an additional perpendicular or tangential direction to the plane of motion; this motion is called joint play by manipulation practitioners and accessory motion (29) by many physical therapists. Joint play includes motions in a nonvoluntary direction as well. Thus, motion restriction in a direction perpendicular to that of voluntary motion will limit voluntary motion in the voluntary direction. This concept leads naturally to manipulation because the practitioner can “gap” (11) the restricted joint allowing a return to a symmetrical balanced seating of the joint, whereas voluntary or active motion cannot.

### Craniosacral Manipulation

Craniosacral manipulative treatment (9,10,30,31) is an approach based on the concept of a primary respiratory mechanism, a cyclic, palpable, rhythmic wave of inherent motion, which corresponds to the Traube-Hering-Meyer wave (a rhythmic variation related to vasomotor tone), and is most easily appreciated in the cranial and sacral areas (32). It is not clear whether this wave is related to low-frequency waves noted in cerebrospinal fluid (CSF) monitoring (32). This primary mechanism is described to include the inherent mobility of the central nervous system (CNS), CSF fluctuation, the articular mobility of the cranial bones, involuntary motion between the ilia, of the sacrum, and the mobility of intercranial and interspinal membranes (30).

The practitioner palpates the head, sacrum, or anywhere on the body to feel pulsations of the postulated wave motion in the 8 to 12 per minute range and for symmetry, amplitude, regularity, and frequency of the wave. In infants and those with head injury, it is easy to accept the concept of motion, but in the normal adult, motion at the cranial sutures must be quite small, animal studies notwithstanding (33). Whether elastic distortions could give rise to these motions or to palpable changes in elastic compliance (34) is unclear. When abnormalities are found, the practitioner uses gentle pressure on the skull and sacral areas to restore the wave to its normal symmetry, rhythm, and amplitude.

At this time, this technique remains controversial, even among some practitioners of manipulation. However, its largest subset of potential patients, infants with birth defects and patients with head injury, intersects strongly with the patient base of many physiatrists, and its recent growth in popularity demands inclusion in any current discussion of manipulation. Importantly, there is some indication that in the head injury population, cranial manipulation can produce undesirable results (35).

### Hypothesis of Mechanism of Action

Manipulation is essentially a mechanical intervention that alters either the mechanical behavior of passive soft tissues or the neural control of the active skeletal muscles that cross a vertebral joint. It is not surprising that almost all the various components of the conceptual framework of manipulative medicine have position or motion of the joint and the soft active and passive tissues that determine these positions or motions as their unifying core. But other than this essential portion, there is wide divergence among practitioners and researchers as to the nature of the dysfunctional problem, its etiology, and what the intervention does to treat it. It is helpful to recognize that various terms refer to the same entity; for instance, minor intervertebral derangement, osteopathic lesion, chiropractic subluxation, manipulable lesion, joint blockage, segmental dysfunction, and somatic dysfunction are all used to describe the same entity. Generally, some pathology, such as fractures, sprains, strains, tears, avulsions, tumors, and joint inflammation, may be

excluded from the various hypotheses because it is generally recognized that manipulation would rarely be considered as primary therapy for those conditions. Fibrotic contractures, sprains, and strains may be exceptions because these may be amenable to manipulation, including, but not limited to, thrust (36).

There are several hypotheses aimed at explaining the cause of somatic dysfunction. Some of the more common of these will be briefly mentioned here, especially as they are more likely to be encountered in physiatric practice.

1. Barrier models have been described by several investigators to explain palpable findings (9,10,37,38) (Fig. 64-2). Normal joints possess an active range of motion and a larger passive range of motion. A barrier or motion restriction may result from abnormal muscle contraction, or capsular or ligamentous shortening across the vertebral segmental joints either in the direction of the intended motion or perpendicular to the joint surfaces that compress them. When a barrier forms between the neutral position and the usual limit, the patient cannot achieve normal range; the manipulator needs additional force to achieve the normal passive range. Asymmetry of the static force may lead to a new resting position for the vertebra, away from anatomic neutral. A variant of this approach considers strain of soft tissue as the basic pathologic condition (23); the resulting inflammation and edema then start a local vicious cycle resulting in pain and hypertonicity.
2. The facilitated segment model assumes that a vertebral body, chronically malpositioned by contracture or overly active muscle, floods the segmentally related area of the spinal cord with inappropriate nonfatiguing proprioceptive impulses. These in turn spill over and facilitate outgoing motor neurons and autonomies in the same vertebral segment of the cord (39). Thus, pathways are present for interaction between soma and viscera at related segments, and palpatory diagnosis of visceral disease and manipulative influence on the viscera are possible. This also allows abnormal segmental areas that were asymptomatic to develop symptoms from general illness, emotional stress, or distant disease. Physiatrists and other physicians familiar with reflex bladders and autonomic hyperreflexia will probably accept the concepts of somatovisceral reflexes and segmental spill-over, but may find the magnitude and importance of these effects in the spine-intact human to be unclear (40,41). Manipulation is thought to release the proprioceptive input by bringing the vertebra to its normal, symmetric position.
3. Numerous hypotheses have been offered by the chiropractic profession to explain the relationships between altered structure and resultant pathologic conditions. These are adequately reviewed by Haldeman (40,42–53). The deleterious neurophysiologic effects that result from nerve compression caused by vertebra derangement have been conjectured to be a major cause of both somatic and visceral complaints. This viewpoint, prominent since the

**FIGURE 64-2.** A model of barrier motion restriction. The motion represented may be rotation, side bending, or flexion-extension. The anatomic barrier consists of cartilage and bony elements, whereas the restrictive and physiologic barriers are made up of muscular and ligamentous elements. (Modified from Kimberly PE. Formulating a prescription for osteopathic manipulative treatment. *J Am Osteopath Assoc.* 1980;79:506–513, with permission.)

earliest foundations of chiropractic, is perhaps the one most associated with chiropractic by other professionals. However, other concepts, including neurodystrophic effects, viscerosomatic reflexes, and a proprioceptive insult phenomenon similar to the segmental facilitation model discussed earlier, also appear.

4. The concept of “ease and bind,” central to functional and other indirect techniques, uses a picture of vertebral motion around a symmetry point where motion in any direction encounters equal tissue resistance (Fig. 64-3). In a lesioned vertebra, the balance point is not the anatomic neutral, so that motion in one direction is met by more resistance (bind) than another (ease) (Fig. 64-4). The maintenance of the asymmetry arises in proprioceptive and  $\gamma$  motor spindle

sensors, and treatment usually involves passive motion to and maintenance of the ease position so that the spindles can reset their output. The strain-counterstrain method suggests that the aberrant activity of the spindles can trigger reflex patterns and trigger points, which can be used to monitor the positional resetting of the spindle output (9,20).

5. The concept of tight-loose refers to the tightness of the fascia around a stimulated agonist muscle and the accommodating looseness of the fascia around the antagonist muscle. This is a central theme in myofascial release approaches to manipulation. The “release” phenomenon is the practitioner’s sense of relaxation of the tight fascia when treatment is successful (9,10).

**FIGURE 64-3.** Schematic representation of normal joint motion in one plane. X-L to the left and X-R to the right demonstrate symmetric range of motion. Tissue tension remains low throughout the arc until the very end of range. (From Johnston W, Friedman H. *Functional Methods*. Indianapolis: American Academy of Osteopathy; 1994:35, with permission.)

### Concepts of Manipulative Treatment

The possible therapeutic effects of manipulation include the following:

1. Passive stretch or even microtrauma (36) to the soft non-contractile tissues (ligament, capsule, tendon, fascia) whose contracture is limiting the vertebral range of motion.

**FIGURE 64-4.** Schematic representation of restricted joint motion in one plane. Even at neutral, resting tone is higher than normal. Motion to the right (X1-R) exacerbates tissue tension or “bind” within a very short range. Motion to the left (X1-L) encounters “ease” or decreased tissue tension. (From Johnston W, Friedman H. *Functional Methods*. Indianapolis: American Academy of Osteopathy; 1994:35, with permission.)

2. Relaxation of inappropriately contracted skeletal muscle whose shortening has limited vertebral joint range of motion. This can happen as a result of changes in the afferent branch of a reflex, by resetting of the muscle spindle equilibrium point or by a change in afferent activity at the vertebral joint’s range endpoint (40,41).
3. Flooding of the cord with proprioceptive or kinesthetic signal to close the gate on pain (54)
4. Endorphin release, although, as noted previously, the data are contradictory on this possibility (43).
5. Placebo effect may be present in manual technique (43). The concept of the therapeutic benefit of human contact, or touch, should not be discounted when discussing any manual treatment.

It should be clear that manipulation success is reported for many, if not most, patients treated with widely varying techniques by practitioners working with very different assumptions as to the cause of the problem and the therapeutic action of the interventions. It would seem that any procedure that induces muscular relaxation or vertebral motion has some chance of success. Because most of the postulated actions of manipulation are accomplished by most techniques, success itself for each technique provides little feedback as to the validity of the various concepts. All, or possibly none, of the hypotheses presented may ultimately be found valid. The placebo effect, which may be diminished or enhanced when the manipulation is relegated to nonphysicians, is impossible to objectively gauge or compare among the various approaches.

### Choosing Manipulation Risks and Benefits

Few risks are involved in manipulative treatment. Complications resulting from isometric or articular treatment have not been reported. There are reports of complications of thrust manipulation to the cervical spine, but the number of reported problems, which is in the hundreds (55), is actually quite small when compared to complication rates of spinal surgery or the use of NSAIDs.

Most recently, cervical manipulation has received attention in the lay press in connection with the development of permanent neurologic sequelae, sometimes with strokelike symptoms (56). This serious and most often reported side effect seems to be related to thrusting style techniques applied to the cervical spine, especially when this region is placed in a position of extension, and without localization to a single vertebral segment at the time of the thrust. It is believed that this type of manipulation, with the cervical spine maximally extended, affects the vertebral artery by causing embolization of plaque material lining the artery. Some basic precautions, including neurological screening examination, with assessment of vertebral-basilar symptoms, and persistent monitoring of the patient during treatment, as well as careful patient selection, can minimize the risk of this rare, but serious, adverse effect.

Osteopathic and chiropractic proponents of manipulative treatment believe in distant visceral benefits, beyond the systemic benefits produced by good structural and biomechanical efficiency and relief of pain (8). However, distant visceral complications temporally related to manipulation have been documented only twice in the past 100 years (57,58); therefore, the physiatrist may safely evaluate the benefits or detriments of manipulation solely on musculoskeletal results.

Benefits of manipulation have been definitively proven to be as effective as NSAIDs and traditional care in the treatment of acute back pain and consensus is growing because it may offer relief in the treatment of acute and chronic low back pain (4,59). Proponents anecdotally report excellent results in treating acute musculoskeletal problems and good results in treating chronic conditions. Empirically, these outcomes are comparable with those achieved with “conventional” modalities, which also often carry no proof of efficacy. The growing number of patients obtaining manipulative treatment indicates at least some degree of perceived benefit.

Few studies have investigated the use of manual medicine in combination with other “standard” treatments, in part because of the potential difficulty separating the additional benefit of manipulation from its counterpart treatment. Most recently, studies have investigated the use of “standard” physical therapy and exercise with and without manual treatments for lumbar spinal stenosis and the use of osteopathic manipulative treatment with acupuncture to treat acute low back pain (60,61). Each of these studies, though small in size, and differing in methodology, found favorable results with combination treatment involving manipulation. Perhaps this is where future research effort, particularly in the physiatric application of manipulation, should be focused.

### Applicability to a Physiatrist’s Practice

The physiatrist should be able to identify, through a focused history and physical examination, that subpopulation of patients most likely to benefit from the incorporation of manipulation into their treatment plan. Although some manipulative techniques may have hospital applicability, for example, rib mobilization in patients with either pulmonary disease or complications from surgery, most patients with conditions appropriate for manipulation are in the outpatient setting. This group includes people with structural problems such as pelvic asymmetries, and vertebral rotations, and others whose diagnosis may rely on palpatory expertise.

While there is a relative dearth of solid research on the use of manipulation, the bulk of what is available addresses what tend to be acute and chronic pain conditions, especially low back pain, treated in the outpatient setting. From these studies, the use of manipulation in acute conditions has been shown to be the most accepted indication (62). The use of manipulation for chronic spinal pain is not yet generally accepted (1,63). Studies (64) are difficult to perform because total eradication of chronic pain is rare, regardless of treatment method employed. Manipulative treatment in these cases should be directed at the restoration of normal spinal segmental motion,

thereby reducing pain, with the hope that overall physical activity might increase (65). As with all treatments for chronic pain, whether there is demonstrable evidence of injury or not, the goal is to assist the patient to adapt, compensate, and continue to function well. An improved understanding of his or her condition can facilitate increased activity, social and vocational reintegration, and self-efficacy.

Objective evidence of the usefulness of manipulation for chronic pain is becoming more apparent. Randomized prospective clinical trials have shown improvement in pain complaints, increased paraspinal pain threshold levels, improved range of motion, and faster return to work (64,66–68). Patients with chronic back pain might be referred for a course of manipulation in conjunction with epidural injections, transcutaneous electrical nerve stimulation (TENS), psychological counseling, and other interventions.

In the inpatient setting, there is little published objective evidence for the use of manipulation. Much of what is written is anecdotal or case-study based. Historically, manual care was successfully used in the 1917 to 1918 influenza epidemic to assist respiratory function and resulted in significantly improved survival rates in persons treated with manipulation (69). Other small studies have been done with hospitalized pneumonia patients and other groups. Extrapolating from these data, it would seem that treating the thoracic region, rib cage, and diaphragm of severely deconditioned or bed-confined persons or those with spinal cord dysfunction might be beneficial and improve tolerance of routine activity or prescribed therapy. Patients with impaired mobility or who have undergone total joint replacement or other surgical procedure, especially if they have concurrent fluid accumulation in the limbs, might benefit from gentle manipulative techniques to assist in fluid mobilization until the patient’s own mobility could do so. Myofascial release techniques could assist in the recovery from trauma-induced issues. Perhaps persons with traumatic brain injury or children with developmental delay could benefit from craniosacral manipulation. Of course, all of these potential treatments come with the advice of careful patient, provider, and technique selection and to follow the “golden rule” of medicine: “First do no harm.”

### Patient Selection

A general physiatric examination should be performed on every new patient. Any underlying impairment must be identified and treated, including fractures, disc herniations with neurologic signs and symptoms, and major sprains, strains, tears, hematomas, and joint injuries. A thorough physical examination, including assessment of gait, posture, muscle tone, muscle stretch reflexes, manual muscle testing, coordination, mental status, and cranial nerves, is strongly recommended prior to initiation of, or referral for, manipulation. Considerations for imaging or electromyography would be no different for the physician using forms of manipulative treatment than for any other type of intervention. There are specific contraindications for thrusting and articulatory manipulation that must be considered, which are discussed below.

Next, the physiatrist contemplating manipulative intervention performs a focused, detailed structural examination in areas suggested by symptoms or by the general examination, with the goal of finding treatable “manipulable lesions.” This evaluation involves careful observation and palpation as well as active and passive motion examination. Subsequent success with manipulation will depend on an accurate diagnosis of lost motion. The findings of palpation and segmental autonomic changes constitute the most important components of structural diagnosis.

The factors generally sought on vertebral or segmental levels are summarized in Table 64-1 (9,70). Passive vertebral motion is evaluated for range, symmetry, quality of motion, and force needed to achieve full range (10,71). Additionally, assessing forward, backward, or side bending and rotation of the vertebra (72) and tenderness elicited by local pressure on the interspinous ligament (70) are useful clues to dysfunctional conditions and loss of joint play. Subcutaneous tissue texture changes (e.g., edema, fibrosis) (72) noted by palpation and skin rolling (10) are signs of dysfunction, and some practitioners look carefully for segmental autonomic changes such as perspiration (10) and hyperemic response to light pressure. The ribs, occiput, and pelvis often need to be included in this part of the examination. Vertebrae identified by positive findings in this type of examination are considered dysfunctional and, if hypomobile, are candidates for manipulation unless contraindications exist.

Hypermobile vertebral segments are themselves not amenable to manipulative treatment (11) but as they may signal the presence of hypomobile segments elsewhere in the spine, should prompt a search for reduced motion elsewhere. If hypomobile segments are found, successful manipulation could conceivably resolve a distant hypermobility. This interconnectedness of the vertebrae is one of the features that make dysfunctions of the spine difficult yet fascinating to study.

A structural examination of this type may add 5 to 10 minutes to an initial visit and less than 5 minutes to subsequent examinations. The physiatrist choosing to manipulate will of course need to do this evaluation with a relatively high degree of acumen and skill. Physiatrists referring a patient to another physician or a therapist for manipulation can probably stop with identification of a hypomobile or tender segment and leave some of the detailed motion analysis to the practitioner providing the manipulation. However, sufficient examination must be accomplished to identify the vertebral segment needing attention and to establish an endpoint of therapy that the physiatrist can verify.

### Modes of Practice

Availability of manipulative treatment depends on which mode of practice is chosen. Physiatrists who wish to use manipulation but not practice it themselves have two alternatives.

### Referral to a Physician

The referral of the patient for concurrent manipulative care to another practitioner works well in many instances (38), but potential problems may occur, such as oversight of the patient's care. This impediment may be addressed through a specific referral that states the exact nature and the scope of treatment requested, that encourages discussion with the referring physician, and that makes clear the intent of the physiatrist to resume the remainder of care, if that is the case. In addition, some physiatrists may be unable to assess the manipulator's competence, and some patients may resent a referral to another practitioner.

### Referral to a Licensed Nonphysician

The second option is for the physiatrist to diagnose the problem and write a prescription for manipulation to be performed by a licensed nonphysician, typically a physical therapist (6). This becomes a viable option as more nonphysicians acquire training in manipulation. In the United States, physical therapists traditionally have been limited to providing isometric and articulatory techniques, although counterstrain and myofascial release techniques are becoming more popular. Manipulation can be provided as part of a comprehensive physical therapy program. Even with such a referral pattern, however, the physician should at least acquire basic palpatory diagnostic skills, which then allows one to write a detailed prescription for an anatomic area to be treated and motion to be restored, along with a suggested technique to be used and frequency and length of treatment. The physician can then monitor progress of the treatment objectively and determine the endpoint and possible side effects or failure of the manipulation. Sequential monitoring of each manipulative intervention can be left to the therapist, given the safety of isometric and articulatory techniques. The acquisition of minimal diagnostic palpatory skills may take 1 to 2 weeks. However, the physiatrist probably will use these skills frequently and maintain them easily. The time commitment and economic investment are far less for this option than in the provision of manipulative treatment itself.

Realistically, many physiatrists allow the practitioner to choose areas of treatment and techniques. This is effective in most cases but can lead to loss of physician direction. Caution must be used to avoid unnecessary continuation of treatment when pain relief does not correlate with biomechanical improvement. If the patient has little to no perceived benefit following four to six appropriate manipulative treatments, the patient should be reassessed by the physiatrist. If the biomechanical deficit persists, additional regions of the patient's body should be reevaluated for their possible contributions to the somatic dysfunction. If the structural lesion is improving, based on the evaluation of the prescribing physician, but the patient does not feel the treatments have been helpful,

additional sessions of manipulation should be approached with caution. Consideration of another type of treatment, or a different provider, should be entertained.

Most physicians employing manipulation believe that restoration of the vertebral joint's normal passive and active ranges of motion and resting equilibrium position is the endpoint of treatment (10). In this view, spinal manipulation is analogous to peripheral passive range of motion and end stretching. It is a natural extension of the physical therapy that physiatrists already prescribe for spine problems because it simply addresses individual joints rather than the spine as a whole.

### Acquiring Manipulation Skills

There are three obstacles to the physiatrist performing manipulation:

1. Acquiring initial skills
2. Maintenance of skills
3. Economics of manipulation

Thrusting types of manipulation, because of the significant forces involved and potential for harm, are best learned on volunteers, not patients, under the close direction of a skilled practitioner. Estimates of the minimum initial learning time required vary from 6 to 8 weeks (7). Even the lower estimates place this type of training out of the reach of many physiatrists. Because of their inherent safety, isometric (muscle energy) and articulatory techniques sufficient for therapy initiation can be acquired by most in 1 to 2 weeks of formal course work. This is so because even an inappropriate isometric technique rarely causes detrimental effects. Thus, the physiatrist may begin working with patients early in training and develop improved techniques with time.

Postdoctoral programs such as those approved by the American Academy of Physical Medicine and Rehabilitation, the American Osteopathic Association, Colleges of Osteopathic Medicine, the American Manual Medicine Association, and other sources can provide a mechanism for the physiatrist to become acquainted with the skills necessary to begin manipulation. There are numerous other courses available that may also be of use to the physiatrist but would have to be investigated individually. There is growing interest among physiatric residents in acquiring this type of training (73), which has led to expanded training opportunities.

The actual minimum frequency of use needed to maintain competence or excellence varies considerably from one person to another. Clearly, however, the potential user should consider maintenance of skills before investing time and money in the acquisition of these skills.

Although any physician can study manipulation techniques, acquiring manipulation skill is demanding, requires practice, and not all physicians will derive satisfaction from providing it. Anecdotally, at least, manipulators who do not enjoy performing manipulation may not do it well.

### Indications for Manipulative Treatment

Manipulative treatment, if there are no contraindications, is applicable in all musculoskeletal pain problems of the back,

pelvis, neck, and limbs in which loss of motion or localized pain on induced motion may be a contributing factor. Some recent injuries (fractures, tears, sprains, strains, disc herniations with neurologic signs, tumors, anomalies, joint disease, inflammation, stenosis) will not respond to manipulation because of the resultant hypermobility, or because local conditions constitute contraindications. Again, all visceral or systemic pathologic conditions, which could manifest through viscerosomatic reflexes must be excluded or at least be under concurrent care.

Although mechanical back and neck pain is the most common indication, other musculoskeletal conditions responding to manipulative treatment have been described. Carpal tunnel syndrome and thoracic outlet syndrome have been shown to improve with myofascial stretch techniques (74–76). Techniques to optimize thoracic cage, clavicular, and scapular motion have benefit in many shoulder girdle problems (10,11). Common sports and repetitive use injuries can be treated with manipulation in conjunction with exercise to restore proper biomechanics (9,77).

### Adverse Effects

Spinal manipulative treatment has a number of reported side effects (78,79). Perhaps the most common is a transient increase in discomfort for 6 to 72 hours after treatment (70). This should resolve to a level less than that of the pretreatment pain and should be less of a problem with each successive treatment. Minor autonomic effects, such as increased perspiration and early or increased menses, have been reported.

### Duration and Frequency of Treatment

Appropriately applied treatment with the correct diagnosis generally produces objective improvement in 2 to 4 weeks (16). Lack of improvement in range of motion or function after 2 to 4 weeks would suggest the need to reevaluate the diagnosis or therapeutic plan. Duration of treatment is determined on an individual basis.

The optimal frequency of manipulative treatment is somewhat difficult to discuss. A search of the literature for a study to answer this question produced no results. Similarly, a review of several major textbooks on manipulation also failed to provide guidelines for treatment frequency. From experience, different practitioners of manipulation have their own preferences regarding style and frequency of treatment. The authors of this chapter feel that duration and frequency of treatment should be based on the condition being treated and the type of manipulation being used. There are undocumented, anecdotal reports of the development of hyperlaxity of ligaments resulting from the use of high velocity low amplitude (thrusting) techniques. The exact frequency and duration required to produce this undesirable effect is not clear. Soft-tissue techniques and indirect treatments, such as counterstrain, and other positional approaches, should allow the patient's body adequate time to respond to each treatment before the same area is treated again, thereby preventing development of proposed reactive hyperlaxity of ligaments that is postulated with

more direct techniques. Another consideration to remember for areas of somatic dysfunction which seem to require frequent treatment to maintain the correction is to expand the physical examination to look for other areas of dysfunction which may be contributing to or causing the lesion in question, and appropriately treat this area first. This will no doubt be the topic for future studies on the use and application of manipulation.

Contraindications

Manipulative techniques differ as to their degree of invasiveness. Because of the higher forces involved, thrust is considered the most invasive, whereas articulation, isometrics, and functional approaches are considered less invasive. The more invasive the approach, the more likely it is to be contraindicated. The literature concerning contraindications for thrusting techniques has been reviewed comprehensively by Kleynhans and others (1,7,80,81); contraindications to articulation are discussed by several investigators (16,82–84).

Absolute contraindications for manipulation, especially nonthrusting techniques, are rare, and relative contraindications are few in number. Clearly, manipulation should only be performed for a hypomobile vertebral segment that might respond to manipulation; therefore, accurate diagnosis is important. Inadequate skill of the practitioner is a major contraindication for all types of manipulation.

Contraindications are summarized in Table 64-2.

Patients with concurrent cognitive or affective disorders may be poor candidates for thrusting interventions (84).

In addition, some investigators consider the absence of any pain-free direction of vertebral motion a contraindication to thrust. Pregnancy with known threat of miscarriage is an absolute contraindication to manipulation. Back pain and intervention in the normal low-risk pregnancy are discussed by Mantle (85). Because the disturbed biomechanics and hormonal ligamentous interactions of pregnancy are frequently implicated in back pain in pregnancy, this subject continues to stimulate discussion in the literature (86–90).

Objective radicular signs are a contraindication to articulation or thrust. The question of manipulation for clearly defined root pain without objective neurological findings is controversial, but most authors appear to avoid forceful techniques in favor of positional interventions (2,38,91–93). Isometrics in a nonlateral position appear to be safe, but there is no conclusive literature on this or any other contraindication to isometrics. Vertebral isometric techniques should not be used if the lesion would preclude passive range of motion, gentle stretching, or isometrics in a peripheral joint with the same condition. Catastrophic results do not occur in isometric techniques; some of the absolute contraindications to thrust and articulation, specifically osteoporosis, central cervical intervertebral disc herniation, rheumatoid disease distant from the cervical area, degenerative joint disease, and joint laxity may become relative contraindications, and patients with these problems probably can be cautiously treated with isometrics. Concurrent active myositis may contraindicate isometrics because of the patient’s active muscular contraction; however, for functional and counterstrain techniques, no contraindications have been documented, but it would seem reasonable to assume these may parallel restrictions against massage, discussed later in the chapter.

Complications

Clearly, complications may occur as a result of procedures that are done despite contraindications. However, the subject needs elucidation beyond that simple statement, best accomplished by discussing cervical procedures and thoracolumbar-sacral procedures separately.

Cervical Manipulation Complications

Several reviews of the literature of complications of cervical spine manipulation have appeared in recent years (12,94–100) including in children. Mild transient reactions to manipulation (78), particularly thrust manipulation, are not uncommon. In cervical manipulation, serious complications involving vascular insult in the vertebrobasilar artery system do occur, although rarely. Almost all are related to thrusting procedures, although this fact can be misleading because the greatest number of manipulations performed involve thrust. Myelopathy as a complication is even more rare (97).

Complicating the review process regarding vascular complications is the lack of available information in the literature specifying number of exposures, vertebral level, localization and direction of thrust, degree of cervical extension, and pertinent patient history. Many of the reported disastrous cases involved

TABLE 64.2    Contraindications for Manipulation
<b>General Contraindications for Manipulation Treatment</b>
Vertebral malignancy
Infection or inflammation
Cauda equina syndrome
Myelopathy
Multiple adjacent radiculopathies
Joint instability (fractures, dislocations)
Cervical rheumatoid disease
<b>Contraindications for Thrust Technique</b>
Systemic anticoagulation
Severe uncontrolled diabetes
Atherosclerosis
Severe degenerative joint disease
Signs and symptoms of vertebrobasilar insufficiency
Spondyloarthropathies
Inactive rheumatoid disease
Congenital ligamentous laxity (Marfan’s, Ehlers-Danlos, Down’s, etc.)
Aseptic necrosis
Local aneurysm
Osteomalacia
Osteoporosis
Acute disc herniation

relatively young patients who presumably had no preexisting vertebral vascular insufficiency and who had undergone prior, uncomplicated cervical manipulation. Haldeman et al. (95) found more spontaneous cases of vertebrobasilar artery dissection than cases associated with thrust manipulation.

The following appear to be reasonable deductions from the review literature regarding vascular complications in patients without contraindications to cervical manipulation:

1. The incidence of cervical complications from thrust manipulation is rare, with best estimates at one case per 1 to 1.5 million manipulations (2).
2. The risk to any given patient is unpredictable and random; provocative testing does not appear to be a sensitive or specific indicator of risk and, given the findings that head positioning alone can lead to insufficiency, may constitute a risk in itself (95).
3. The risk of nonthrust cervical manipulation would appear to be very small compared with that of thrust manipulation, but the paucity of documented cases makes even an estimation impossible.
4. It seems reasonable to avoid excessive cervical extension because this position may compromise the vertebral artery system.
5. It is prudent to avoid cervical manipulation in any patient with objective signs and symptoms referable to the vertebrobasilar system, cervical spondylosis, or spinal instability.

### Thoracic and Lumbosacral Manipulation Complications

Severe complications following thoracic and lumbosacral manipulation are very rare and appear to have been limited to thrust procedures. The most serious is the development of a cauda equina syndrome (101). Many of the cases in the older literature actually involved manipulation under anesthesia, which is rarely used today. The incidence of such severe complications, even when the potential for unreported cases is included, is estimated to be 1 in many millions; recent reviews (12,102–104) address the issue. There are no documented or anecdotal reports of serious complications arising from articular, functional, isometric, soft-tissue, myofascial release, or counterstrain techniques.

### Prescribing Manipulation

The referral of a patient for manipulation requires a prescription. This can be, and perhaps is best done, through conversation with the provider, implying the physician has chosen a practitioner with appropriate credentials and training. The manipulative care will usually be included as part of a general ranging, strengthening, and educational program. What will be added to the prescription are the specific vertebral region to be manipulated, the suggested technique to be used, and any specific side effects or medical issues the provider must be aware of. For example, a patient with low back pain, for whom demonstrable pathology has been ruled out, with the palpable

finding of hypomobility of T-12 relative to L-1, would have a prescription as follows:

*Patient age:* \_\_\_\_\_

*Precautions:* Avoid thrusting techniques

*Diagnosis:* Unresolved mechanical low back pain without radiographic or neurologic findings

Somatic dysfunction T-12

*Rx:* Back stabilization program

Back education program

Muscle energy procedures to T-12 to restore normal T-12 mobility relative to L-1

Home program

*Frequency:* Three times per week

*Duration:* Three weeks or until T-12 motion is normalized

*Options:* May use soft-tissue massage before manipulation, may use superficial hot-cold modalities to supplement above. Please call to discuss other treatment options if indicated.

*Other:* Notify physician if patient complains of increased pain lasting more than 8 hours after last session. Notify physician when mobility in T-12 relative to L-1 is normalized.

Follow-up patient examination, in this case to confirm the restoration of T-12 mobility, occurs as with any other treatment program. If unsuccessful, reformulation of the diagnosis or of therapy would follow. The next step might be escalating the invasiveness of the manipulation to articular or thrusting techniques, if no contraindications exist. Conversely, if manipulation is producing discomfort lasting greater than 8 hours, consider switching to the less invasive counterstrain or functional techniques.

The manipulation technique used will be determined by the time course of the problem, the patient's age, general physical condition, presence of any contraindications, and expertise of the practitioner. The former considerations explain the need for a careful history, physical examination, segmental structural examination, and functional diagnosis, whereas the last justifies the choice of a particular practitioner for a problem. The provider should be allowed some input to the technique or approach, with agreement reached before therapy is initiated. A manipulable lesion must be identified for manipulation to be effective for any patient; this is particularly important for the subacute or chronic population that the physiatrist frequently encounters. Patients cannot localize muscular forces to a particular segment or joint in the spine; thus, self-mobilization of the vertebra is not feasible. The manipulative process will therefore always need to be performed by a practitioner. Also, it should be remembered that there is rarely complete eradication of pain in these patients. These factors lead to the possibility of dependence on manipulation, and the physiatrist should be aware of this possibility. Having well-defined biomechanical endpoints (i.e., normal range of motion and tissue compliance) will help objectify the endpoint to manual treatment. If pain relief alone is used as an endpoint, treatment could continue indefinitely. There is no well-established literature on this point, but experience with chronic pain patients suggests that manipulation, with accompanying physical therapy, should be

directed at obtaining an optimal biomechanical condition as quickly as possible, and thereafter used only infrequently to “tune up” the mechanics as needed. There is no evidence that prolonging care is in the patient’s best interest.

### Research Relevant to Manipulation

There probably is no other medical modality that has had so many practitioners (50,000 doctors of osteopathy and chiropractic in the United States), consumers (90,000,000 chiropractic manipulations alone are performed annually in the United States), and critics with so little hard data to support or refute it.

The difficulties inherent to the study of manipulative interventions (105) are formidable and include the lack of a well-defined placebo treatment, of well-accepted outcome measures and agreement as to what procedures should be included or excluded, and of objective physical methods of quantifying the preexisting and posttreatment biomechanical state, the parameters of treatment, what procedure to use, and what duration of treatment should be investigated, to name a few. Even more confounding is the lack of basic understanding of the plethora of causes of musculoskeletal pain, the poorly understood relationships between pain generators and outcome, neurophysiologic and biomechanical changes, and the blurred boundaries between acute and chronic pain. The net result is that, despite encouraging trends, hard scientific proof of efficacy remains elusive.

### Procedural Fundamentals

The basic mechanics of thrust manipulation have received much attention recently and are well summarized (106). Research in this arena continues to be done (107), but the other methods of manipulation have not been examined to determine their biomechanical and neurophysiologic bases of action, despite major advances in our understanding of the related areas of pain and mechanoreceptors (44), spinal cord physiology (44,108), disc pathology (45), and normal spinal biomechanics (46–50,109).

Two areas of research development are strikingly absent. One involves the lack of any firm association of somatic dysfunction (arthrodial and myofascial restrictions) to pain (36). Although somatic dysfunction is the entity treated by manipulation, the nearly universal reason for treatment is pain relief. However, the relationship between these two basic concepts is ignored even in the hypothesis stage of most concepts. The second area involves the absence of any instrument or device that can objectively measure somatic dysfunction in a patient.

Most physiatrists see patients who present with problems potentially treatable by manipulation and who have undergone manipulation or soon will, in some setting. At the very least, therefore, physiatrists should know the types of manipulation their patients might encounter, along with associated contraindications. Only some physiatrists will actively refer patients, usually those failing to improve with initial therapeutic interventions for manipulation, and few will fully incorporate manipulation into their own practice.

A.T. Still, M.D., the founder of osteopathic medicine taught that, through knowledge and facility with anatomy and physiology, physicians should understand how to apply manipulation principles to the body. For this reason, he never wrote a textbook of techniques, nor specific formulaic instructions, for treatment of a given body part or ailment. Since his time, many types of providers of manual care have published many such books and manuals, each of which applies its own perspective upon a concept and provides variations of one or more similar techniques and terminology. There is ongoing debate among manual medicine practitioners over which group was first and which techniques are the best. It is unlikely that this will be settled in the foreseeable future. It is probably best to rely on the experience and skill of an individual practitioner to provide appropriate manipulative treatments, rather than limit one’s referrals to only one type of provider.

Regardless of the type of manipulative treatment chosen, perhaps one of the most important things to keep in mind is that it is not a “stand alone” treatment. Physiatry is a medical specialty that has pioneered and embraced the “team approach” to patient care; the incorporation of manipulation as another part of the treatment armamentarium can fit well within its paradigm. One may choose pharmaceutical therapy for hypertension, spasticity, or other conditions; however, when it comes to physiatric application of manipulation, a combination of manual and other therapies may be the best approach.

Manipulation in the United States is now well over 100 years old; more research should be generated regarding its use. Ongoing concern about health care cost containment will demand answers to questions of its mechanism and efficacy, as in all areas of medical practice. An objective validation is daunting, given the present level of knowledge; although much of medical practice is not based on objective findings, efforts should continue to maximize current objective data. Until these questions are resolved, the physiatrist must evaluate manipulation based on incomplete information, as in other areas of physiatric practice (Table 64-3).

## MASSAGE

Massage is one of the oldest treatment modalities in medicine (110,111). Throughout history, it has been woven into the cultural context of medicine. In this sense, it may be viewed as an essential component of traditional medicine, with the word “traditional” implying an old and very common usage. Massage may be classified into Western and Eastern variants. In the West, mentioned as early as the time of Hippocrates (111), its practice and popularity have waxed and waned over the centuries. The interested reader can find detailed accounts of the history in various sources (111–117). In recent years, its popularity has increased by a resurgence of interest in alternative therapies (114). Some claims for massage by its proponents may sound implausible, but there can be little doubt that it is considered efficacious for a wide variety of conditions

**TABLE 64.3**   **Key Points for Manipulative Treatment**

The goal of manipulative treatment is restoration of lost joint motion and improved postural balance.
Thrust, articulatory, counterstrain, functional, muscle energy, myofascial release, soft tissue, and craniosacral are common techniques used in manipulative treatment.
Although the exact mechanism of action is unknown, manipulative treatment appears to alter the mechanical behavior of static musculoskeletal structures and the neural control of muscle.
Indications for manipulative treatment include acute and chronic spinal pain of mechanical origin and overuse injuries of the extremities.
Benefits are generally observable after 2 to 4 weeks of appropriate treatment.
Complications are exceedingly rare, although serious vascular compromise has been reported with thrust technique in the cervical spine.
Although methodologically sound studies are lacking, most research and consensus suggest a modest benefit of manipulative treatment in mechanical spinal pain.

(115–118). There is a striking need for additional research regarding its mechanisms and efficacy.

**Definition and Relation to Other Mechanical Therapies**

Massage is the therapeutic manipulation of the soft tissues of the body, with a goal of normalization of those tissues. It is also defined as “hand motion practiced on the surface of the living body with a therapeutic goal,” (118) or, “a group of procedures which are usually done with the hands, such as friction, kneading, rolling, and percussion of the external tissues of the body in a variety of ways, either with a curative, palliative, or hygienic object in view” (119).

Manipulation and massage both involve similar hand positions and movements, and some techniques overlap significantly. Soft-tissue manipulation, performed to loosen and relax tissues before vertebral or more direct manipulation, is partially composed of massage techniques. Myofascial release (120) uses stretching forces similar to those used in massage. Myofascial release and craniosacral manipulation, discussed in the manipulation section of this chapter, are often available from massage therapists, and massage can easily be a preliminary treatment to manipulation. Regardless of the similarities, massage clearly targets the health of the soft tissues, whereas manipulation often targets vertebral or segmental motion; soft-tissue health is optimized secondarily with manipulation.

The difference between massage and traction is easier to delineate. Massage consists mostly of hand movements, some of which may be traction based. Traction as a therapy usually involves machinery but can also be applied manually; the latter would not use other massage movements. In addition, traction tends to effect changes in the spinal column, with soft tissues only secondarily modified. Like traction, massage effects tend to be nonspecific.

Massage can have mechanical, reflexive, neurologic, and psychological effects and can be used to reduce pain or adhesions, promote sedation, mobilize fluids, increase muscular relaxation, and cause vasodilatation (121,122).

**Basic Western Massage Procedures**

There is perhaps more confusion in the terminology of massage than in many other areas of manual medicine. Much of the basic terminology for Western massage was introduced by Pare (123) in the first half of the 20th century, but there is a tendency for textbooks and practitioners to use idiosyncratic variants. The essence of massage is the use of the hands to apply mechanical forces to the skeletal muscles and skin, although the intent may be to influence either more superficial or deeper tissues. The types of massage prevalent in the Western hemisphere are derived from the Swedish system. They are categorized by whether (a) the focus of pressure is moved by the hands gliding over the skin; (b) soft tissue is compressed between the hands or the fingers; (c) the skin and muscle are impacted with repetitive compressive blows by the hands; or (d) shearing stresses are created at tissue interfaces below the skin. The three former techniques retain their classic French names, *effleurage*, *pétrissage*, and *tapotement*, whereas the fourth is called deep friction massage.

**Effleurage or Stroking Massage**

The operator’s hands glide across the skin overlying the skeletal muscle being treated (112,113,115–117,120,124). Oil or powder is often incorporated to reduce the friction between the hands and the skin. Any part of the hand can be used, but many applications require the palm to be in contact with the skin. In all stroking techniques, hand-to-skin contact should be maintained throughout the stroke. If the compressive force on the muscle is kept relatively light, this is called *superficial stroke massage*; if relatively heavy, it is *deep stroke massage*. Presumably, a light stroke energizes cutaneous receptors and acts by some neuroreflexive or vascular reflexive mechanism, whereas a deep stroke is more capable of mechanically mobilizing fluids in the tissues beneath it, including the muscle, in the direction of the stroke. Therefore, deep stroking should be in the direction of venous or lymphatic flow, whereas light stroking can be in any direction.

Effleurage tends to be a technique common to all massage therapy because it is used to gain initial relaxation and patient confidence, to diagnose regions of spasm and tightness, and most importantly, to get the operator’s hands from one problem area to another, where other techniques may be employed. Effleurage has as its main mechanical effect the application of sequential pressure over contiguous soft tissues, with the result that fluids will be displaced ahead of the hands as the tissue is compressed.

**Pétrissage or Kneading Massage**

Kneading massage involves compression of the underlying skin and muscle either between the fingers and thumb of one hand or between the two hands of the practitioner. The

entrapped tissue is squeezed gently as the hands move in a circular motion perpendicular to the direction of compression (112,113,115,116). Some investigators call this “kneading” the tissue, whereas others separate kneading from *pétrissage*, depending on the direction of the compression and force of the motion. The pressure is such that the skin can move over the underlying tissue, but practitioners disagree on whether the operator’s hand should slip relative to the skin. Mobilization of fluid would be a result with this type of treatment, but *pétrissage* has as its main mechanical effect the compression and subsequent release of soft tissues, reactive blood flow, and neuroreflexive response to that flow.

### Tapotement or Percussion Massage

The operator strikes the soft tissue with repetitive blows using both hands rhythmically, gently, and rapidly (112,113,115,116). There is no rigid frequency requirement, but typically these motions occur about three times per second (117). There are numerous variants defined by the part of the hands that make the impact; using the back of the medial fingers is called *backing*; the volar surface of all the fingers is called *slapping*; the hypothenar eminence is called *beating*; the pads or the tips of the fingers is called *tapping*. If the thumb and index finger do a light pinch on contact, it is called *pincement*. A form more familiar to physicians occurs when the cupped palm of the hand is used to make the impact. This tends to make a clapping noise on each impact. The therapeutic effect is hypothesized to result from a compression of trapped air that occurs on impact. Because the frequency of sound is low, the waves can penetrate to deep structures, but whether this is the therapeutic effect is not clear. If done over the upper back, the lung tissue may absorb the waves; a variant of this technique, called *clappatage*, is used by respiratory therapists to loosen bronchial secretions.

The effect of tapotement is thought to be stimulatory. It tends to be used more often on healthy people by nonmedical practitioners in a nontherapeutic milieu. Nonetheless, it also is part of the armamentarium of medically trained practitioners.

### Friction or Deep Friction Massage

Pressure of varying intensities is applied with the ball of the thumb or fingers to the skin and muscle of the patient. The digit is moved with constant pressure in small circular motions for several cycles before pressure is released and the application performed in a new location (112,113,115,116,125). There is no gliding, as in *effleurage*, and no compression between the fingers, as in *pétrissage*. The main mechanical effect of friction massage is probably the application of shear stresses to underlying tissue, particularly at the interface between two types of tissue (e.g., dermis-fascia, fascia-muscle, muscle-bone, scar tissue-bone). It is probably impossible to affect abnormalities within one tissue (e.g., muscle). The effect of the pressure is to keep superficial tissues under the thumb from shearing so that the shear and force are directed to a deeper interface. The higher the applied pressure, the thicker the plane of non-gliding tissue and the deeper the level that shear takes effect.

Various techniques have the motion across fibers, parallel to fibers, or in random fashion. Friction massage is perhaps the primary method of preventing or treating adhesion of scar tissue to bone and deeper structures. For this reason, physiatrists involved in amputee rehabilitation may encounter this application more often than other techniques.

All of these techniques have variants, and each has its proponents. A variant of tapotement, called vibration, differs in that the hands do not lift off the skin at the end of each cycle. Variants of *pétrissage* depend on the forces applied to the tissue trapped between the fingers or hands. The technique of picking up requires the tissue to be first compressed against deep structures, pinched, then released for advancement of the hands to a new area for treatment. Wringing requires one hand or finger of the practitioner to push the trapped tissue while the other hand pulls, perhaps shearing even deep tissue planes between them. Rolling, which is often done just to the skin in diagnosis of manipulable lesions, allows the tissue to roll between the fingers and thumb, often combined with gliding of the digits over the skin. In shaking, entrapped tissue is shaken by the operator’s hand as it glides down the length of tissue.

Each of these variants arises by changing the dominant force used, then adding a new sequence of shear, compression, or glide that basic techniques provide. For a given patient, the correct combination of these forces may be more important than the sequence of their application.

### Decongestive Lymphatic Therapy

Decongestive lymphatic therapy, also known as complex decompressive therapy, includes manual lymphatic drainage (MLD) in addition to use of specifically prescribed compressive bandages and garments, as needed, along with exercises and skin care (126). MLD consists of gentle massage in the treatment of lymphedema. Proximal areas are treated first to prevent a damming effect. The treatment is designed to stretch the lymphatic collectors and to stimulate the drainage system. The massage is followed by the application of compression bandages and is incorporated into a comprehensive and individualized self-care program (127,128).

### Eastern Massage

Eastern massage systems have evolved over many centuries and are integrated within the culture of the country where they are practiced. The systems for evaluation, diagnosis, and treatment for the most part are not based on known Western neurophysiology. It is evident that Western massage is incorporating some of the more valuable Eastern concepts (129). Many of these techniques resemble variants of classical Western massage, although they are often used for visceral complaints. There are many more variations of technique, as many as 24 in one Chinese system (130).

### Acupressure

Acupressure applies massage forces, largely digital pressure, to the same points treated with the better known acupuncture

needles, and for the same reasons (112,113). Energy, or Chi, is said to circulate in the body along 12 meridians or pathways unrelated to the neuroreferral patterns known to Western medicine. Imbalances of energy found along the meridians are thought to cause disease and can be rectified by localized finger pressure accompanied by circular movements similar to deep friction. The pressure is generally increased until it is relatively heavy and then held constant. The similar Japanese form is called Shiatsu and the Indian form is Marma therapy (129,131).

### Reflexology and Auriculotherapy

The meridian concept is also a part of the reflexology and auriculotherapy systems (112,113). The meridians are thought to have whole-body representation like a homunculus on the extremities, particularly the feet, hands (reflexology), and the ear (auriculotherapy). All parts of the body and its organs are mapped to points on the foot or ear, and massage of a point is thought to produce change in the organ or structure mapped to that point (131).

### Massage Variables

There are variables of massage that need to be controlled by the operator (112,113). The physiatrist may wish to specify these if ordering massage, although often they are left to the provider. The environment should provide comfort and relaxation to the patient, with proper adjustment to the temperature, lighting, sounds, draping of the patient, and so forth. Media such as oil or powders may be used to reduce friction. Rhythm rate and pressure are applied according to the effect desired, that is, a rapid rate for stimulation versus a slower rate for relaxation. The amount of pressure is also varied. In lymphedema, it is thought that low pressure assists in the flow, whereas higher pressures may cause damage to the lymph vessels. The direction of stroking, as well as the sequencing of the regions, is important in aiding the flow of fluids. Peripheral to central stroking moves fluids toward the core, but central to peripheral sequencing prevents a proximal damming effect. A cross-fiber stroke helps reduce adhesions in the deep friction techniques.

The areas to be treated, as well as the duration and frequency of treatment, should be specified by the referring practitioner. Treatment goals are also helpful. The patient may wish to continue the treatment after goals have been attained. This could be helpful when the patient understands the transition from a treatment program to a wellness maintenance program.

### Physiologic Effects

#### Mechanical Effects

Vascular changes are recognized as a clear mechanical effect of massage. Mechanical pressure on soft tissue displaces any fluids that are not chemically bound by the tissue or physically bound by compartmentalization. The fluid can move in a low-resistance direction under the static hand force, but a moving locus of pressure will create a pressure gradient. Assuming no significant resistance, pressure is lower ahead of (usually

proximal to) the advancing hand. Once the mobilized fluid leaves the cells or interstitium, it can enter the low-pressure venous or lymphatic systems, with valvular mechanisms that help prevent fluid return. Areas are typically worked distal to proximal, centripetally, to keep the fluid movement toward the heart, which, along with the kidneys, is required to handle an additional load. The amount of fluid mobilized in any one treatment is probably quite small, and major effects to the heart have not been noted. Nonetheless, the physiatrist needs to be aware of this physiologic effect in the patient with cardiovascular or renal compromise. Proponents of the “decongestive lymphatic therapy” approach to lymphedema, espousing gently applied massage, tend to massage the proximal lymph area first, and then move distally. The belief is that proximal blockage areas in the lymph channels must be opened first, perhaps reflexively, to allow subsequent distal mobilization of the fluid and protein (122,123,132–134). Studies have shown a 59% to 69% reduction in limb volume with sustainable long-term responses (135,136) and others have not (137,138).

Kneading and stroking massage both decrease edema, and compression will convert nonpitting to pitting edema (139). Friction massage is probably not effective in this regard. In addition to that strictly mechanical effect, it is thought that histamine is released by the massage, causing superficial vasodilation to assist in the washing out of metabolic waste products (121,122). Venous return is thereby increased, and in healthy patients, stroke volume will increase (140). There is contradictory evidence that massage to one limb will increase the blood flow contralaterally (141,142). If this is true, the mechanism is uncertain. Effleurage may be more effective than either diathermy or ultrasound in increasing blood flow to congested or damaged tissue (143). Clearly, these effects on the mobilization of fluids are more important in the flaccid or mechanically inactivated limb because the normal compression supplied by skeletal muscle contraction is absent in those cases.

Recent findings suggest that massage may decrease blood viscosity and hematocrit and increase circulating fibrinolytic compounds (144,145). Although these are preliminary data, it would help explain the apparent success of massage in decreasing instances of deep vein thrombosis (146). Massage nonetheless is still contraindicated in the presence of existing thrombosis. Other blood compounds that may be transiently increased by massage include myoglobin, glutamic oxaloacetic transaminase, creatine kinase, and lactic dehydrogenase (147,148). One may suspect that these transient increases represent local muscle cell leakage from applied pressure. Lactate does decrease in massaged muscle cells (149). An increase in natural killer cell numbers has been documented in many massage studies (150). Massage is said to decrease muscle spasm and increase force of contraction and endurance of skeletal muscle (151,152). One can rationalize the decrease of spasm and the increase of endurance as occurring secondary to washout of metabolic waste products by the mobilization of fluids and increased blood flow. The enhanced contractual force, however, is based on remote publications and needs new investigation, validation, and elucidation, particularly because the mechanism is

not obvious. A decrease in muscle soreness is probably from the washout of metabolites, and the cycle may be broken permanently if the spasm was responsible for the original buildup of the metabolites and immobility of the muscle. A number of studies support the benefit of sports-specific massage, with other studies showing contradictory results (153).

The shearing forces of deep friction massage have not been studied adequately, but it is accepted that they can break down or prevent adhesions and increase fascial mobility (116,117,125,154,155). Limited local tissue damage, with hyperemia and mild inflammation, may occur when adhesions are reduced.

A special case of the mechanical effects of massage on the lymphatic system is the “lymphatic pump” often used as part of manipulation techniques for patients with respiratory compromise (156). This is a type of *pétrissage* done to the chest and rib cage that is hypothesized to draw lymph into the patient’s thoracic duct and hence to the venous circulation because of the alternating increase and release of pressure on the chest cavity.

Similar to manipulation, it has been postulated that endogenous endorphins are released by massage (121,157). Here, too, there is little supportive evidence, and further studies are needed to establish this effect either way (158).

### Reflexive Changes

Massage can stimulate cutaneous receptors and possibly the spindle receptors in superficial skeletal muscles (122). These produce impulses that reach the spinal cord, which, once there, conceivably can produce myriad effects (121,122,159). One such effect would be moderation of the facilitated segment, an area of impairment that develops a lower threshold for irritability when other areas are stimulated (160). Somatovisceral reflex effects on the viscera are possible in this model, although evidence for this is lacking. Our knowledge of somatovisceral and viscerosomatic reflexes is rudimentary enough to consider almost any effect, but allowing for such a system, massage could have distant visceral effects. Others might include input to the “gate” of the dorsal column of the spinal cord, thereby reducing pain like a mechanical TENS unit (159). The increased afferent input may influence the activity of the cord itself. Some of the vascular effects noted previously could be secondary to reflexive vasodilation, although one might justifiably question why vasoconstriction does not also occur. It does seem safe to acknowledge that reflexive effects occur in massage, with further details awaiting scientific validation. One method of massage that depends heavily on reflex mechanisms, and that may be encountered by the physiatrist, is the German *Bindegewebsmassage*, or connective tissue massage (112,161,162). This is based on the concept that autonomic vascular, rather than somatic, nerves are the channels for reflex systems that give rise to skin symptoms or palpatory changes, not necessarily along accepted dermatomes. The skin massage here is done very lightly, presumably in areas related to the viscera, to influence the connective tissue, trigger reflex mechanisms, and ultimately modify the target viscera. Studies of

its effects are contradictory (163–166). Some of the Eastern approaches to massage noted earlier (reflexology, auriculotherapy, and Marma therapy) are also dependent on reflexive mechanisms, most of which have little or no basis in conventional Western neurophysiology and neuroanatomy.

These types of hypothetical postulates, which are difficult to prove and even more difficult to disprove, form the basis of massage and manipulation and of practitioners’ efforts to effect visceral or reflex changes with these methods. There are few, if any, complications of massage that cannot be explained on purely mechanical or well-established physiologic grounds. A recent discussion of the ability of somatic problems to mimic visceral pathology may be the first step in understanding some of these approaches (167).

### Psychological Effects

Most people experiencing any form of massage will attest to the feeling of relaxation and well-being that it produces. Whether this is a placebo effect or the result of some hitherto undiscovered reflex is unknown, but this has stimulated interest in the use of massage for acute and chronic pain conditions as well as in anxiety states (111,150,163,167–169). Some practitioners incorporate a variety of other psychological techniques, such as guided imagery, into the massage treatment. Another massage approach which incorporates psychosomatic integration is *Rolfing* (after the originator) or *structural integration* (170). *Rolfing* incorporates deep friction massage aimed at realigning and balancing the patient’s body relative to the gravitational field, with predetermined sequences of treatments which may be unrelated to individual symptomatology. The rebalancing is thought to optimize both the psychological and physical states of the patient.

### Therapeutic Goals of and Indications for Massage Therapy

Massage is used either as a therapeutic intervention alone or more commonly as an adjunct to other modalities. It is indicated by a need for one of its physiologic, reflexive, or psychological effects, as noted previously. Thus, it might be ordered to mobilize interstitial fluids, to reduce or modify edema (171–178), to increase local blood flow, to decrease muscle soreness or stiffness, to moderate pain, to prevent or eliminate adhesions, or to facilitate relaxation.

In a physiatric practice, these indications may be considered in patients with sprains, strains, and fractures; mechanical back pain; contractures; myofascial pain syndromes with accompanying tightness, myoedema, and spasms; flaccid or immobilized limbs; amputations; and sympathetic dystrophy (179). In these patients, massage may be used to alter the pathophysiology of the primary condition (e.g., contracture) or to prevent or modify the negative ramifications of the primary treatment modality (i.e., nonobstructive limb edema from immobilization). The physiatrist will most frequently be involved with the chronic sequelae of these impairments, and massage is, perhaps, more useful in chronic rather than acute conditions. In almost all cases, however, massage is secondary to and less important

than the primary treatment therapies (i.e., immobilization, ranging, strengthening) and must be used in such a way that it acts synergistically with and not antagonistically to them. The sedative effect may be of complementary use in any of a large number of painful or anxiety-stimulating conditions.

### Contraindications

Massage is contraindicated when it would cause worsening of a condition, unwanted destruction of tissue, or spread of the condition (112). Malignancy, thrombi, atherosclerotic plaques, and infected tissue could be spread by massage, and their presence is thought to be an absolute contraindication to massage. Relative contraindications include the treatment of scar tissue that is not fully healed; patients who are anticoagulated, either therapeutically or by disease; calcified soft tissues; skin grafts; inflamed tissue; atrophic skin; and tissue that is susceptible to further edema if circulation is increased by the massage technique.

Although not rigidly a contraindication, chronic pain situations must be approached cautiously by the physiatrist if massage is going to be used. Because it has a passive, hands-on nature and potentially strong psychological effects, the risk for dependency of the patient is always present. Patient satisfaction, of course, may increase with this type of approach, but objective improvement in the impairment may not occur. To use massage for chronic pain, endpoints must be established before institution of the treatment and treatment must be terminated when they are reached.

### Practical Problems in Physiatric Application of Massage

Four practical issues may confront the physiatrist. First, patients who have already undergone massage require some action on the part of the physician. Many patients will have received massage directed at relaxation, sometimes ordered by physicians as a therapy for stress relief, but more often entered into by the patient by means of self-referral. Although this type of therapy is seldom directed primarily at musculoskeletal problems, the practitioners often have varying degrees of experience in athletic training or other such vocations and thus may address musculoskeletal issues in the course of the massage. An accurate history of the patient's experience is relevant, and the physiatrist may wish to consider including the massage therapist in the overall care plan. At the very least, intervention when contraindications are present may become the responsibility of the physician.

The second practical issue facing the physiatrist committed to the use of the massage is the choice of a therapist. Competent practitioners in a therapeutic milieu may be physical therapists, occupational therapists, athletic trainers, nurses, or respiratory therapists. Massage therapists trained in therapeutic techniques may also be found in the clinical setting. When the massage is to be used as an adjunct, the choice is usually dictated by the concomitant therapy. Thus, the type of provider chosen often may depend on skills other than massage. Most physical therapists and many occupational

therapists receive massage training during their professional education. Massage involves as much art as science, though, and different providers might obtain markedly different results with what appear to be identical techniques. Thus, trial and error and local reputation and credentials are probably the most useful criteria involved in the choice of a specific massage practitioner.

A third issue is the cost and insurance coverage of massage treatment. Massage alone is sometimes reimbursed but generally needs to be bundled into the overall therapy plan to be viable for most patients. This usually acts to the patient's benefit for several reasons. Accompanying therapies tend to prevent dependency on massage, particularly in chronic pain conditions. Second, the other therapies involved usually have well-established functional endpoints that can be used to justify the overall program and validate its composite efficacy, an issue of some importance with massage alone. In those few cases in which improved function is not the main desired outcome (e.g., the cosmetic result of lymphedema reduction), the physician may have more difficulty establishing the usefulness of massage. Finally, a massage prescription may need to be generated, particularly if a long-term program is anticipated; such a prescription should include the relevant diagnoses, precautions, areas to be treated, verifiable goals, and specific massage variables discussed earlier. The physician cannot determine some of these variables a priori because tissue feedback often guides the provider, but the physician can delineate treatment parameters.

### Efficacy

Long-term efficacy of massage has not been validated in most of the previously noted conditions. Most applications of interest to the physiatrist involve a limited course of therapy directed at permanent improvement of a condition. The situation is analogous to the use of an antibiotic to cure an infection as opposed to an antihypertensive medication designed to be used indefinitely. Long-term effects are therefore of paramount interest, but have not been investigated. One issue is that the underlying physiology of the tissues is not well understood so that it becomes difficult to understand how massage would affect that physiology. At this time, the therapeutic use of massage must be undertaken with the understanding that its value lies either in demonstrable short-term improvements (such as decreased edema, soreness, and sensitivity) or in longer-term verifiable outcomes of the accompanying therapies that it facilitates.

Given the interest in and use of massage in the face of increasing scrutiny of health care expenditures, it is important that the long-term efficacy of this modality be established scientifically, including accurate outcome measures. In addition, entry criteria to identify the subset of patients most likely to benefit from massage would be useful. Massage continues to provide a valuable modality for physical medicine practitioners since it is user friendly (albeit potentially time intensive and expensive), of low risk, and does not rely on technology (180,181). As a result, it is available worldwide and has the potential to continue to provide valuable future health benefits.

## TRACTION

Traction is the act of drawing or pulling, or a pulling force. In medicine, forces are applied to the body generally to stretch a given part or separate two or more parts. Traction continues to be effectively used in the treatment of fractures of the extremities and the spine. In physiatry, traction is usually limited to the cervical or lumbar spine, with the hope of relieving pain in, or originating from, those areas, and this section addresses only spine traction.

Since the days of Hippocrates, attempts at correction of scoliosis have frequently involved traction in one form or another. Treatment of long bone fractures led to the development of many traction techniques in the 1800s (180). More recent attempts at spinal traction have included applying the pulling force manually (181), with free weights and a pulley (182), with the patient supplying the pull with his hands or feet (183), with motorized equipment (184), by inversion and gravity supplying the pull (185), and using partial body weight support in conjunction with treadmill walking (186).

### Physiologic Effects

#### Cervical Spine

The most reproducible result of traction to the cervical spine is elongation. Cyriax reported that applying a force of 136 kg (300 lb) manually results in a 1 cm increase in cumulative interspace distance (181). A study to determine optimal weight for cervical traction concluded that the minimum weight to accomplish any vertebral separation is 11.6 kg (25 lb) (187). Greater forces (188), and in some cases much greater forces (189), have been used, but most studies have concluded that elongation of 2 to 20 mm of the cervical spine is achievable with 11.3 kg (25 lb) or more of tractive force. In another investigation, the anterior and posterior intervertebral spaces (IVS) and the facet joint space at neck positions of 30 degrees of flexion, neutral, and 15 degrees of extension were quantified under 13.6 kg (30 lb) of intermittent traction (8 seconds of traction followed by 6 seconds of rest) after a total traction time of 20 minutes. The anterior IVS was increased most in 30 degrees of flexion, ranging from 18% to 21%, with the largest IVS at C6-7. The effect of traction on the facet joint was, in all three positions, not statistically significant. Many subjects in the study noted that traction in neck extension was painful, and the posterior IVS actually decreased in some instances. The investigators, citing these reasons, in addition to the increased risk for complications from vertebral basilar insufficiency and the possibility of spinal instability, did not recommend the use of traction in extension (190). The vertebral separation accomplished after traction has been reported as temporary, with return to normal height the morning after traction (188). The effect of traction on paraspinal muscles is not well known. Cyriax postulated that traction leads to fatigue and then relaxation (181). However, another study found greater muscle relaxation in the cervical traction group with 0.9 kg (2-lb) placebo traction than in a group using 2.7 to 5.4 kg (6 to 12 lb) of traction (191,192).

#### Lumbar Spine

After friction is overcome with either adequate force of pull (193) or a split table (194), the major physiologic effect of traction of the lumbar spine is elongation. Investigators who report widening of the lumbar interspaces used between 31.7 and 136 kg (70 and 300 lb) of pull to obtain that result. The widening, when apparent, averages up to slightly more than 3 mm at one intervertebral foramen (195–198). The length of time that this separation persists remains indeterminate, with one study unable to document residual distraction 30 minutes after treatment (197) and another demonstrating residual separation at least 10 minutes after treatment, which was the endpoint of the observations (199).

Data have been generated on the dimensional and pressure changes caused by traction in lumbar discs, both in the normal spine and after herniation. A decrease in the intradiscal pressure of patients treated with 22.7 to 45.4 kg (50 to 100 lb) of traction on a split table has been documented (194), but there is evidence that some such applications actually cause an increase in intradiscal pressure that, in principle, would exacerbate nerve compression from a herniated component of the disc (200). Discograms performed during both compression and distractive traction showed large variations (>10%) of the radiologic disc area in patients with “disc syndrome,” but failed to demonstrate area changes in normal subjects (201). Reduction of prolapsed discs during lumbar traction has been noted by epidural contrast (202) and an unblended computed tomographic scanning technique at short-term follow-up (203). The latter study was marred by lack of both blinding and long-term follow-up. Thus, the evidence is inconclusive, with considerable information favoring at least temporary reduction of the herniated component of an abnormal lumbar disc under the influence of traction.

The issue of whether the disc changes size does not directly address pressure relief on the nerve root or reversal of abnormal physiology in radiculopathy. This much more clinically relevant question has received surprisingly little attention in the literature to date. However, a study by Knutsson et al. demonstrated an improvement in lower extremity voluntary muscle strength and normalization of bilateral somatosensory evoked potentials and skin temperature (by thermography) after autotraction (see below) in patients with lumbar and sacral radiculopathies (204). Unfortunately, the investigators were not blinded, and controls and long-term follow-up evaluations were not included. Nonetheless, this research breaks ground in the area of inquiry that is of most interest to physiatry. It should be noted that there is a tendency for some physicians to use lumbar traction as a means of enforcing bed rest (205,206). The benefits of strict bed rest for low back pain are questionable, and its physiologic effects are discussed in Chapters 55 and 57.

### Evidence-Based Outcome

There are few scientifically rigorous studies in the literature that allow the effect of traction to be distinguished from the natural history of the pathology (usually radiculopathy) being treated.

Deyo has suggested criteria that would allow the true effects of traction to be delineated in the face of confounding variables. Studies meeting these criteria should use (a) randomized, controlled trials; (b) blinded outcomes assessment; (c) equivalent cointerventions; (d) monitored compliance; (e) minimal attrition; (f) minimal contamination; (g) adequate statistical power; (h) adequate description of study design, patients, and interventions; and (i) relevant, functional outcomes (207). There is probably only one group of studies evaluating traction in nonspecific low back pain that comes close to this rigorous level of evidence (208–210). No other traction outcome study to date has satisfied all these criteria. Despite this, there are randomized, controlled trials that meet many of these and give clinicians some insight into the efficacy of traction.

### Lumbar Traction

In 1994, the AHCPR reviewed the literature on traction and made recommendations as part of the clinical practice guideline on acute low back problems in adults. Thirty-one articles were examined, of which six randomized, controlled trials met criteria for their review. Additionally, the panel did a meta-analysis of traction. The AHCPR conclusion was that “spinal traction is not recommended in the treatment of acute low back problems” (211). This is a strong, negative recommendation that does not appear to be refuted by other randomized, controlled trials using good methodology. Recent evidence-based literature reviews support the 1994 conclusions (212–215).

The highest quality trial is published in a series of three papers which report the methodology and results of a high-quality, randomized, controlled trial of 151 patients with nonspecific low back pain between 6 weeks’ and 6 months’ duration. A sham treatment of a brace that tightened in the back was used. Wide ranges of outcome measures, including work attendance at 4 weeks, 12 weeks, and 6 months, were used. The investigators could not show any statistically significant benefit from traction (216–218).

The studies that claim improvement after traction report modest, short-term improvements with limited or no improvement in functional outcome and have study design flaws. Some examples of these illustrate the lack of convincing evidence for traction efficacy. Eighty-two patients with acute sciatica and positive straight-leg-raising signs were assigned randomly to either corset and bed rest (not timed controlled placebo) or autotraction (219). Evaluation was performed 1 and 3 weeks after treatment by a blinded observer and after 3 months by questionnaire. Traction subjects were treated either as outpatients, who were usually driven home by ambulance, or as inpatients. Placebo controls did not have the time-intensive ambulance rides or overnight hospital stays. Although no outcome differences between those treated with traction and those treated as controls were apparent after 3 months of follow-up, the traction-treated group reported modest pain relief without documented functional improvement 1 and 3 weeks after treatment.

Pain relief has been reported in patients who were treated with traction for 6 days for a chief complaint of back pain and

sciatica (220). This improvement was limited to a subgroup of women younger than 45 years of age, follow-up was only 2 weeks, and functional outcomes were not measured. Another investigation showed that patients with sciatica treated with traction and exercise had more favorable pain improvement than a cohort treated with hot packs, massage, and spinal mobilizing and strengthening exercises. The actual control group in this study received a placebo therapy of hot packs and rest and had similar improvement to the traction group. Nonetheless, these similar results were interpreted as a “significant priority” for those treated with pelvic traction (221). Other controlled trials evaluating primarily patients with sciatica do not report clear benefit for traction (222–226). Of course the “absence of proof is not the proof of absence.” It is entirely possible that a subgroup of patients (e.g., lateral herniated discs with radiculopathy) can benefit from a particular type of traction for either short-term or long-term improvement in functional outcome. At this stage, the literature does not clearly delineate these subgroups and, overall, suggests no benefit from traction.

### Cervical Traction

Few randomized, controlled trials address patient outcome after cervical traction. Methodology problems are similar to those noted previously regarding lumbar traction. A review of the randomized, controlled trials available will give clinicians an idea of the potential efficacy and limitations of cervical traction.

Perhaps the most ambitious trial was conducted by the British Association of Physical Medicine and published in 1966. A total of 466 neck and arm pain patients were randomly assigned into one of five groups: (a) traction; (b) placebo traction (positioning); (c) instruction in posture and cervical collar; (d) placebo as untuned short-wave diathermy; and (e) placebo tablets. A blinded assessment was performed at 2 and 4 weeks, with letter follow-up at 6 months. Outcome measures included range of motion, pain, and function. There was no statistical difference between the groups and no noticeable trends in subgroups. The authors suggest that none of these treatments alters the natural history of the problem. The major potential criticism of this study is that the traction treatment was not completely standardized. The investigators reported that the traction was “given every chance to succeed,” and thus the therapist had latitude to customize the traction (227).

Three randomized trials have reported improvements in patients treated with cervical traction. Goldie and Lundquist reported the results of a randomized, controlled trial in 73 neck and arm pain patients who were placed into one of three groups: (a) traction; (b) isometric exercises; and (c) instruction only (no time-controlled placebo) (228). There was slight improvement in both of the treatment groups over no treatment, with patient report, blinded physician report, and ranges of motion used as outcome measures. Of note, there was no difference in sick leave taken, although there was a trend for less time off work in the instruction only group. Zylbergold and Piper reported on a controlled trial of 100 patients randomized into

one of four groups: (a) static traction; (b) intermittent traction; (c) manual traction; and (d) nontraction treatment (hot packs, exercise, and range of motion not strictly time-controlled with other traction groups) (229). Blinded observers noted that the intermittent traction caused improvement over the other three treatments in range of motion (neck flexion and rotation). Klaber-Moffett et al. reported a statistically significant improvement in neck range of motion in patients receiving continuous traction (191,192). Although statistically significant changes were reported in these studies, the actual clinical significance of 5 to 10 degrees of neck movement is unclear. Measures of pain, sleep disturbance, social dysfunction, and activities of daily living did not show statistically significant improvement in the traction group. Recent evidence-based reviews on acute, subacute, and chronic neck pain suggest that cervical traction is not effective in the treatment of these conditions (215,230,231).

## Techniques of Applying Traction

### Manual

Cyriax has written most extensively about manual application of spinal traction primarily as an adjunct or precursor to spinal manipulation (97,232).

### Cervical

Traction generally is transmitted to the spine by a free weight and pulley system or an electrical motorized device. Adequate pull for the cervical spine is achievable by using a head or chin sling attached to a system that can provide pull in a cephalad direction. The motorized devices have the advantage of allowing easy application of intermittent traction but require the patient to be in the clinic. Free weight and pulley systems have been developed for home use. Many units for home traction consist of a bag filled with 9.1 kg (20 lb) or more of water or sand, and a pulley system attached to a door. If a tractive force of only 9.1 kg (20 lb) is possible, then the system probably will fail to achieve therapeutic results because one half of that weight counterbalances the head in the sitting position (233), and only a suboptimal 4.5 kg (10 lb) of traction remains. This limitation has led to the development of supine cervical traction units that sacrifice only a few pounds of pull to overcome friction. Cervical traction should not be attempted at home alone because if patients get into uncomfortable positions, they may need help removing the device. Additionally, most of these systems are difficult for the patient to set up without assistance. Home cervical traction can cause an increase in pain or fail to produce significant pain relief unless it is professionally monitored periodically. Improper head and neck position and inadequate tractive force lead to ineffectual therapy. At the initiation of home traction, the patient should demonstrate proper use of the equipment to the satisfaction of the therapist. This demonstration should be repeated at intervals, starting at 1 week and gradually progressing up to 2 to 4 weeks; compliance and scheduling of this home traction regimen may not be practical.

### Lumbar

Adequate pull with weights and pulleys or a motorized device (203) to achieve vertebral distraction also can be attained in the lumbar spine with the proper apparatus. A harness is usually attached around the pelvis (to deliver the caudal pull), and the upper body is stabilized by a chest harness or voluntary arm force (for cephalad pull). Motorized units have the relative advantage of allowing intermittent traction with less therapist supervision. If the goal of traction is distraction of lumbar vertebrae, then 31.8 to 68 kg (70 to 150 lb) of pull is generally employed (206). The friction between the treatment table and body usually requires a traction force of 26% of the total body weight before there is any effective traction to the lumbar spine (193). Thus, if lumbar traction were applied to a 90.7 kg (200-lb) patient, the first 22.7 kg (50 lb) of traction would not be therapeutic to the lumbar spine. Many traction devices use a split table that essentially eliminates the lower body segment friction (234). There are very few practical home lumbar traction units.

### Gravity

Theoretically, body weight provides sufficient pull to distract lumbar vertebrae and eliminates much of the necessary mechanical apparatus. Gravity traction is used almost exclusively for lumbar traction. Inversion traction is accomplished by patients hanging upside down with their feet strapped in special boots. After 10 minutes of inversion traction, there has been documented increased intervertebral foraminal separation (198). However, reported side effects have included increased blood pressure, periorbital and pharyngeal petechiae, persistent headaches, persistent blurred vision, musculoskeletal pain, and contact lens discomfort (235). The use of inversion therapy has greatly decreased in recent years, and many clinicians feel the risks outweigh the benefits. Other gravitational lumbar traction systems involve corsetlike vests worn around the ribcage, causing the patient's feet to be lifted from the ground with the weight of the legs and pelvis supplying the traction force to the lumbar spine (197,235). Recently, this type of suspension has been combined with a treadmill to allow exercise and normal activity during traction (186,236). This gives the theoretic advantage of increasing activity during traction, creating a more active form of traction. Another form of gravity-assisted traction is anecdotally reported to reverse scoliosis temporarily.

### Autotraction

Autotraction devices allow the patient to provide tractive forces by pulling with their arms on a specially designed table (183,198,237,238). One randomized treatment trial with nonblinded observers suggested that autotraction was more efficacious than passive traction (239).

### Parameters

As with many other areas of physiatric therapeutics, little has been proved about the most efficacious parameters for traction. Preferences of specific parameter settings (e.g., sitting vs. supine,

continuous vs. intermittent) depend more on the practitioner's empiric observation than on objective data. Individual physicians should, within limits dictated by common sense and the experiences of others, develop personal guidelines regarding the amount of weight, duration of traction, and other parameters. Above all, the patient should be comfortable during traction therapy. Monitoring by the physical therapist is essential to ensure that the traction applied is not ineffective or aggravating a painful condition.

### Positioning Cervical

In cervical traction, the choice of sitting versus supine positioning should be based on patient comfort and ability to relax. Crue was the first to suggest the importance of neck position in cervical traction (240,241). This may be related to widening of the intervertebral foramina or IVS. The maximal effect of distraction seems to occur between 20 and 30 degrees of flexion with no accompanying rotation or side bending (190,242). Nearly all studies report difficulties with the cervical spine in extension; thus, neck extension during traction should be avoided (190).

### Lumbar

Lumbar traction can be accomplished with upright body suspension, but chest discomfort from the harness is often a limiting factor (197); thus, the supine position is most commonly chosen. Hip flexion (15 to 70 degrees) is routinely incorporated to cause relative lumbar spine flexion, theoretically leading to optimal vertebral separation. Reliable studies comparing different positions of lumbar traction are lacking.

### Continuous Versus Intermittent Traction Cervical

A larger improvement in range of motion with less accompanying pain was noted in patients subjected to intermittent traction of 11.4 kg (25 lb) peak (10 seconds on, 10 seconds off, total duration of 15 minutes) than in cohorts subjected either to 15 minutes of manual traction or 15 minutes of static traction of 11.4 kg (25 lb). All three groups were treated with the cervical spine flexed at 25 degrees (229). Data show that a constant cervical distraction force of 13.6 kg (30 lb) effects maximum vertebral separation in 7 seconds or less and that no more is gained by applications of 30 or 60 seconds (199). If so, then strictly skeletal effects require no longer application times in order to be optimized, but, of course, accompanying musculoligamentous relaxations (181) may require much longer times of application. These studies, in conjunction with the fact that patients may prefer the improved comfort of intermittent pull, suggest some advantage to an intermittent over continuous protocol (187,229,243).

### Lumbar

There is limited information on this topic for lumbar traction. Cyriax has reported that continuous traction is necessary to fatigue the muscles and allow strain to fall on the joints (181).

Despite this claim, no statistical difference in x-rays was noted for normal subjects treated with either continuous traction of 45.4 kg (100 lb) for 5 minutes or intermittent traction of 45.4 kg (100 lb) peak for 15 minutes (10 seconds traction, 5 seconds rest) (182). Similarly, the data seem conclusive for the skeletal effects, but it is conceivable that some of the benefits of traction occur in the soft tissues, which may respond much differently in terms of sensitivity to time. Again, improved patient tolerance seems to favor the use of intermittent traction (184).

### Weight Cervical

If cervical traction is performed with the patient in the sitting position, about 4.5 kg (10 lb) is required to counterbalance the patient's head (233). Amounts less than this may be used initially to condition the patient to the feel of the halter and pull. In the literature, there is a great deal of variation, with the amount of force reported varying from 2.7 to 200 kg (6 to 440 lb) of traction (244). Colachis and Strohm have shown that 13.6 kg (30 lb) of traction to a neck flexed to 24 degrees can cause vertebral separation, particularly posteriorly, but an increase of force to 22.7 kg (50 lb) produced no clear-cut additional separation (242). This correlates with the earlier finding that a minimum of 11.4 kg (25 lb) was needed before the vertebrae separated (187). An initial "test dose" of 2.3 or 4.6 kg (5 or 10 lb) of traction followed by a gradual increase in weight to 20.4 or 22.7 kg (45 or 50 lb) has been advocated (187).

### Lumbar

Friction becomes an important consideration in the lumbar spine. In a widely quoted article, Judovich reported that a pull equal to about one half the weight of a body part is needed to overcome friction: for the lower body, this becomes 26% of total body weight (193). Either this amount of force needs to be applied before true traction on the spine is accomplished or a split table must be used (193,234,245). Regardless of whether the effect of friction is overpowered or bypassed, another 25% or more of body weight is then needed to cause vertebral separation. For example, Colachis and Strohm used 22.7 and 45.4 kg (50 and 100 lb) of lumbar traction with a split table and measured statistically significant vertebral separation with both weights (182). Posterior vertebral separation predominated at 22.7 kg (50 lb); anterior and posterior widening occurred at 45.4 kg (100 lb). The usual range of traction is between 31.8 and 68 kg (70 and 150 lb), averaging 45.4 kg (100 lb) (206,246). With tractive forces above 45.4 kg (100 lb), the counterforce, in the form of a chest or axillary harness, causes pain and is the limiting factor for many patients.

### Duration Cervical

The exact and optimal duration of traction has not been clearly shown. Recommendations have varied from 2 minutes to 24 hours for each session (229). Intermittent traction with the

neck in flexion for a total traction time of 15 minutes (229), or 20 minutes (190), or 25 minutes (196) has produced physiologic effects. A duration of 15 to 25 minutes, if tolerated by patients, is commonly prescribed. There is also significant variability in the frequency of application and duration of program parameters ranging from daily for 2 months to two or three times per year. Traction is commonly prescribed at a frequency of daily for the first week, then every other day (or three times per week) for a total treatment time of 3 or 4 weeks. Most reported trials use 10 to 15 sessions over a 3- to 4-week period (227–229,244).

### Lumbar

The information pertinent to duration of force application is limited and does not allow definitive judgments to be made. In cadavers, 85% of lumbar elongation retraction occurred immediately (247). Others have applied traction for 5 minutes to 8 hours (188,197,198). Lumbar traction with minimum weight often has been used for many days to enforce bed rest without the expectation of the physiologic effect of the traction itself. Treatment is typically recommended for 8 to 40 minutes per session (206).

Recommendations for frequency are similar to those for cervical traction, that is, daily for the first week, then every other day (or three times per week) for a total treatment time of 3 or 4 weeks. Most reported trials use 10 to 15 sessions over a 3- to 4-week period (206,227–229,244,246).

For both cervical and lumbar traction, goals of treatment should dictate the time course and determine the endpoint of treatment. Potential endpoints of treatment include (a) pain relief; (b) normal range of motion; (c) return to work or appropriate activity; (d) exacerbation of symptoms during treatment; (e) inability or unwillingness of patient to schedule traction; (f) lack of improvement in symptoms or activity any time after four to six sessions of traction; and (g) 3 or 4 weeks of traction. Any of these can be used for individual rehabilitation programs depending on the role of traction in the overall program.

### Indications for Traction

The literature does not give clear indications for what type of neck or low back pain can benefit from traction. In fact, most studies strongly suggest that traction does not significantly influence the long-term outcomes of neck or low back pain (248). Thus, defining indications in the face of poor scientific evidence of efficacy is very difficult. Physicians who prefer sound scientific evidence for the efficacy of treatment probably rarely use traction for spinal pain. Balancing the scientific evidence, there are numerous anecdotes of cases in which traction seems to have helped individual patients, making many clinicians and patients willing to give traction a trial. Without additional scientifically valid outcome studies, it is likely that spinal traction as a treatment for neck and back pain will gradually diminish. For clinicians who are willing to recommend empiric treatments, the indications for traction are outlined subsequently.

Theoretically, if traction can separate vertebrae and decrease the size of herniated discs, then patients with this

problem and radiculopathy would be the most likely to benefit. Indeed, most studies attempt to target this population, with little demonstrated efficacy. There is considerable disagreement among investigators. Weinberger has suggested that traction is “irrational, counterproductive, nonphysiologic, and traumatic” (249). Yates has stated that there is no reason to suggest that traction will be any more useful to treat degenerative spondylosis of the cervical spine than traction to a hip or knee with osteoarthritis (250).

### Cervical

Cervical traction has been used for a wide spectrum of painful conditions based on its physiologic effects of vertebral separation, widening of the intervertebral nerve root foramina, and possible reduction of herniated disc material and muscle relaxation. Neck and arm pain has been historically used as the indication (227).

### Lumbar

Low back pain caused by herniated nucleus pulposus, lumbar radiculopathy, or muscle spasm might improve with appropriately applied traction of adequate force (231). Additionally, some clinicians use lumbar traction as an enforcement of bed rest in the treatment of acute low back pain. There are no data to suggest that painful or nonpainful radiculopathy with clear neurologic deficit will benefit from traction.

### Contraindications

There are few anecdotes and no scientific reports that clearly delineate the contraindications of traction. Thus, clinicians must rely on empiric information and opinion to guide them. Old age is a relative contraindication, given the likelihood that at least one of the described conditions is more likely to be present in elderly people. Should a practitioner wish to prescribe traction for an elderly person, a careful screening process should be used.

In general, the following are considered contraindications to cervical or lumbar traction: ligamentous instability; osteomyelitis; discitis; primary or metastatic bone tumor (251); spinal cord tumor; severe osteoporosis; untreated hypertension; severe anxiety; clinical signs of myelopathy; or inadequate expertise of the practitioner providing the treatment.

Cervical traction requires additional considerations. Patients with vertebral basilar artery insufficiency could theoretically experience a stroke due to traction, particularly with the neck in extension. In elderly patients, it is difficult to eliminate the diagnosis of vertebral basilar insufficiency. Thus, patients with a history at all suggestive of vertebral basilar insufficiency should not have cervical traction. Additionally, patients with rheumatoid arthritis and other connective tissue disorders are at high risk for atlantoaxial instability. This also may be difficult to diagnose, and thus patients with rheumatoid arthritis should undergo cervical traction with extreme caution, if at all. Patients with midline herniated nucleus pulposus or acute torticollis should not have cervical traction (176).

Lumbar traction has fewer factors that require special consideration. However, patients with restrictive lung disease or other breathing disorders should not be subjected to the pull of a chest harness. Additionally, the following have been listed as contraindications without supporting evidence: pregnancy, active peptic ulcers, hiatal hernia, other hernias, aortic aneurysm, gross hemorrhoids, and evidence for cauda equina compromise (251). If there is any remaining question of spine instability after evaluation of the patient, imaging studies, especially flexion-extension x-rays of the spine, should be considered.

### Writing the Referral

The practitioner can no more write “cervical traction, please” as a treatment prescription than to ask for “physical therapy for back pain” or “medications for infection.” One is obliged to write a detailed parameter-specific prescription for cervical or lumbar traction. As with other physical therapy referrals, the following patient information is included: age, gender, diagnosis, underlying medical conditions, precautions to be taken, patient symptoms that would signal a need to discontinue the traction, and recommended medical follow-up.

Cervical or lumbar traction should not be used as a single modality but rather as one aspect of an overall rehabilitation program. Traction as a modality to improve activity, mobility, and function (e.g., return to work) is probably most effective. If patients are required to miss 2 to 3 hours of work per day to undergo traction and physical therapy, one could argue that this is an ineffective treatment and may actually be counterproductive to the patient’s overall recovery and well-being.

The patient’s interests are not served by writing a prescription for a home cervical traction unit and expecting a pharmacy clerk to explain its use, nor is lumbar traction reliably self-applied by the patient at home. The therapist’s input therefore becomes critical to the successful and safe use of traction. If traction for any reason exacerbates symptoms, it should be discontinued and the efficacy and rationale of continued traction should be closely examined. There is no evidence to date to suggest that the patient should “endure the side effects” of traction in order to enjoy its therapeutic effect.

The following specific parameters should be outlined in all traction referrals:

#### Position

Body position: sitting, supine, standing, or walking on treadmill

Neck position (cervical traction): between neutral and 30 degrees of neck flexion

Hip and knee position (pelvic traction): full extension to 90 degrees of flexion

#### Mode of Application

Continuous or intermittent: Intermittent is preferred for patient comfort. Various times have been used (e.g., 7 to 15 seconds of traction with 5 to 10 seconds rest or 30 to 60 seconds of force with 10 to 20 seconds of rest). Some equipment

allows adjustment of the time required to reach maximum pull (rise time).

#### Weight

A range is necessary to allow patient acclimatization. Usually, a small amount of traction is used at the beginning, with additional weight added later.

Cervical: 2.3 to 20.5 kg (5 to 45 lb) (starting low and gradually increasing or decreasing each session or over a number of sessions).

Lumbar: 22.7 to 68.1 kg (50 to 150 lb).

#### Other Modalities

Superficial heat for relaxation may be used before or during traction.

#### Time

In most instances, 10 to 30 minutes.

#### Frequency and Duration

Three to five times per week for 3 to 6 weeks.

#### Physician Reevaluation

Two to 14 days.

#### Guidelines for Discontinuation

If symptoms become worse or new symptoms develop (e.g., pain, dizziness, weakness, autonomic symptoms), traction should be discontinued.

#### Goals and Endpoint

Delineating endpoints that the physiatrist can identify is helpful. Some of these are discussed above in the section on “Duration.” Working on protocols with therapists can be useful.

#### Home Traction

If a supervised trial of cervical traction is successful, a home unit can be prescribed with the contingency that the therapist checks the patient for correct head and neck positioning and for the use of adequate weight, initially and at intervals. The monitoring interval may vary depending on the patient but will likely increase over time.

### The Future of Traction

Traction has a long history of clinical acceptance based on surprisingly little understanding of its mechanism of action or proof of its efficacy. Although it seems natural to associate separation of the vertebrae with relief of pressure on the spinal nerves in situations in which herniated discs are present in the lateral recesses, little or no evidence exists for this mechanism. Even if it does occur in this manner, the question arises as to whether the pressure relief is permanent and, if not, whether it is reasonable to believe that a neuropathic process will reverse itself in the short time the separation is present. If not, then might not some of the perceived benefits result from

changes in the musculoligamentous system through relaxation, vasodilation, neurologic reflexes, or other numerous mechanisms that might occur? Twenty years ago, these questions were unanswerable, but current imaging and physiologic instruments are able to evaluate neurologic, muscular, and soft-tissue structures. Unlike manipulation, which deals with normal but dysfunctional tissue (i.e., no clear neurologic damage), traction generally has been studied in patients with apparent abnormal structure. Perhaps traction really only addresses the soft tissues, and the wrong subset of patients (neck or back pain secondary to radiculopathy) has been evaluated.

It seems difficult if not impossible to document the actual prevalence of the use of traction in clinical practice; based on anecdotal discussions and the paucity of recent literature on the subject, it appears that its use has diminished significantly over the past few years. It would be unfortunate if traction were to fall completely out of favor because no one has used modern technology to study it. This is particularly true at a time when spine pain is a growing societal burden, and no other highly effective treatments appear on the horizon.

# Pharmacotherapy of Disability

## ANALGESICS

The treatment of patients with pain is a major focus of many outpatient physiatric practices and is becoming even more important since the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) mandated pain as the fifth vital sign and Congress declared, as of January 1, 2001, that this is the Decade of Pain Control and Research. Physiatrists, therefore, should have familiarity with analgesics. This section is organized by grouping analgesic medications into classes and presenting them in simple alphabetical order (Table 65-1).

### Overview of Pharmacologic Pain Management by the Physiatrist

Analgesics, particularly opioids, are being prescribed with greater frequency. Although pain can be classified as nociceptive or neuropathic, patients often present with mixed pain syndromes (1). The current optimal medication choice for neuropathic pain is unclear, even though a better understanding of the pathophysiology of neuropathic pain suggests that nonopioid agents, such as antidepressants and anticonvulsants, should be more efficacious than opioids or nonsteroidal anti-inflammatory drugs (NSAIDs). Although clinical studies have not consistently demonstrated this, the many confounding factors involved in neuropathic pain states make study interpretation difficult (2).

## ANALGESIC MEDICATIONS

### Acetaminophen (Tylenol)

#### Relevance to Physiatry

Although acetaminophen is unsatisfactory as a single agent for patients requiring a powerful analgesic, it can be an effective primary or adjuvant medication for pain of mild to moderate intensity. In particular, it is considered to be the initial medication of choice for patients with osteoarthritis (OA) of the knee or hip who present without obvious signs of inflammation (3). Acetaminophen is also an alternative for some patients who experience gastrointestinal (GI) side effects with NSAIDs or celecoxib or who are at particular risk for renal toxicity associated with these agents. In addition, it is often used in combination with both opioid and nonopioid analgesics so as to decrease potential side effects (and thereby lessen interference with a rehabilitation program) by lowering the dose

requirement of these other medications. In contrast to aspirin, it is often used in the pediatric rehabilitation setting due to the lack of an association with Reye's syndrome.

Other potential uses for acetaminophen include headaches for which it can be used as a single agent or as a combination product with various narcotic analgesics as well as with butalbital and caffeine (i.e., Fioricet or Esgic). Acetaminophen is also the primary agent used to suppress fever in the inpatient rehabilitation setting.

Acetaminophen has negligible anti-inflammatory effects; it, therefore, cannot be substituted for anti-inflammatory agents when treating conditions such as rheumatoid arthritis.

Due to the potential for chronic acetaminophen overdose leading to hepatotoxicity, patients must be counseled to not exceed dosage limitations when taking scheduled doses of acetaminophen. Patients also might not realize that over-the-counter (OTC) headache or cold/flu remedies often contain acetaminophen, and this can lead to inadvertent overdose if they are also prescribed acetaminophen either in the form of Tylenol or in combination with analgesic medications.

### Mechanism of Action and Pharmacokinetics

Despite clinical use of acetaminophen for over 120 years, its exact mechanism of action is still under investigation. Studies have confirmed a pathway whereby acetaminophen decreases production of prostaglandins by reducing prostaglandin H<sub>2</sub> synthase, a COX enzyme (4). This mechanism is notably distinct from NSAIDs, which physically block arachidonic acid from accessing COX enzyme's active site, and is hypothesized to explain its diminished action at anti-inflammatory sites—where the activated immune system produces oxidizing agents that can reverse the reduction step.

Acetaminophen is rapidly and almost completely absorbed from the upper GI tract. It is then uniformly distributed throughout the body, partly bound by plasma proteins while the unbound portion exerts the therapeutic effects. Acetaminophen can penetrate both the placenta and blood-brain barrier (5). It is swiftly metabolized in the liver and excreted by the kidneys at its recommended dosage.

### Preparations and Dosing

The brand name Tylenol is frequently used interchangeably with the generic term *acetaminophen*. There are three major oral Tylenol preparations and they are shown in Table 65-2, which lists the dosing regimens that would provide a maximum dose of

**TABLE 65.1**    **Abbreviation Key**

μg	mu microgram	LSD	lysergic acid diethylamide
ACE	angiotensin converting enzyme	MAOI(s)	monoamine oxidase inhibitor(s)
Ach	acetylcholine	mg(s)	milligram(s)
ADP	adenosine 5' diphosphate	MI(s)	myocardial infarction(s)
AED	anti-epileptic drug	mL(s)	milliliter(s)
AF	atrial fibrillation	MT	multiple trauma
AF/flutter	atrial fibrillation/flutter	Na+	sodium
APAP	acetaminophen	NE	norepinephrine
aPTT	activated partial thromboplastin time	NMDA	<i>N</i> -methyl-D-aspartate
ASA	aspirin	NNT	number needed to treat
AV node	atrioventricular node	NO-NSAIDs	Nitric oxide NSAIDs
bid	twice per day	NSAID(s)	nonsteroidal antiinflammatory drug(s)
BNZs	benzodiazepine(s)	OA	osteoarthritis
BP	blood pressure	OTC	over the counter
BUN	blood urea nitrogen	PO	by mouth
$C_{max}$	maximum concentration	PR	by rectum
Ca <sup>2+</sup>	calcium	PCP	phencyclidine
CaCB(s)	calcium channel blocker(s)	PE	pulmonary embolus
cAMP	3',5'-cyclic adenosine monophosphate	PRN	as needed
CBC	complete blood count	PSVT	paroxysmal supraventricular tachycardia
CHF	congestive heart failure	PT	prothrombin time
CNS	central nervous system	PVC	premature ventricular contraction
COPD	chronic obstructive pulmonary disease	q	every
COX-II	cyclooxygenase-II	qd	once per day
CVA(s)	cerebrovascular accident(s)	qid	four times per day
DA	dopamine	Q wk	weekly
DP	dipyridamole	qod	every other day
DVT	deep venous thrombosis	RVR	rapid ventricular rate
ECG	electrocardiogram	SC	subcutaneous
ER	extended release	SCI	spinal cord injury
FDA	Food and Drug Administration	SL	sublingual
GERD	gastroesophageal reflux disease	SP	substance P
GI	gastrointestinal	SR	sustained release
H/S	at bedtime	SSRI(s)	selective serotonin reuptake inhibitor(s)
H <sub>2</sub>	histamine 2 receptor	SVT	supraventricular tachycardia
HDL	high-density lipoprotein	$t_{1/2}$	half-life
HIV	human immunodeficiency virus	TBI	traumatic brain injury
HTN	hypertension	TCA	tricyclic antidepressant
IM	intramuscular	TD	transdermal
INR	international normalized ratio	THA	total hip arthroplasty
IR	immediate release	tid	three times per day
IV	intravenous	TKA	total knee arthroplasty
JCAHO	Joint Commission on Accreditation of Healthcare Organizations	UFH	unfractionated heparin
LDL	low-density lipoprotein	V tach	ventricular tachycardia
LFTs	liver function tests	VLDL	very low-density lipoprotein
LMWH	low-molecular-weight heparin	WBCs	white blood cells
		VF	ventricular fibrillation

**TABLE 65.2** Acetaminophen Preparations and Dosing for Adults

Tylenol Formulation	Acetaminophen Content	Dose (Maximum No. of Units)
Tylenol	325 mg	2 tabs q4h
Extra-strength Tylenol (ES-Tylenol)	500 mg	1 tab q3h or 2 tabs q6h
Tylenol arthritis	650 mg	2 tabs PO q8h

4 g per 24 hours for those patients with normal hepatic function. For those with abnormal liver function, specific dosing information should be consulted prior to prescribing. Acetaminophen is also available in liquid and suppository preparations.

### Relevant Side Effects and Drug Interactions

Acetaminophen has an extremely favorable side-effect profile when used within recommended dosage limitations (6). In those with normal hepatic function, the maximum daily recommended dose is 4 g/day. Precaution must be taken when it is used

1. Chronically in excess of the recommended dose
2. At more than approximately 2 g/day in patients who consume excessive amounts of alcohol (defined as more than three alcoholic drinks/day)
3. When taken as a single dose in excess of approximately 15 g. Fatalities in children due to accidental overdose were reported and OTC cold medicines in the United States were subsequently withdrawn for children under 2 years of age

Acetaminophen is metabolized into an intermediate, *N*-acetyl-benzoquinoneimine, that accumulates and may cause fatal hepatic necrosis (7). While the liver is the primary target of toxicity, chronic use of acetaminophen is also associated with renal failure (8). However, aside from cases of overdose, acute nephrotoxic effects of acetaminophen are not common in the nonalcoholic population (9). The National Kidney Foundation, for this reason, has not amended its 1996 recommendation, making acetaminophen the drug of choice for analgesia in those with renal dysfunction (10).

Acetaminophen has a very favorable medication interaction profile. One potentially important exception, however, is warfarin as large acetaminophen doses can potentiate its effect by prolonging its half-life (11). Although this is believed to only be clinically significant in patients with a relatively high international normalized ratio (INR), the INR should be monitored in patients who are chronically taking acetaminophen while also on warfarin (12).

### Antidepressants Relevance to Psychiatry

Because depression is a common consequence of illnesses and injuries, particularly if they are associated with functional loss, psychiatrists should familiarize themselves with this medication

class. Antidepressants are also used off-label to treat chronic nonmalignant pain syndromes and neuropathic pain (13–15). Not only do these agents treat the psychiatric component of chronic pain, but there is also evidence that they have independent analgesic effects (16,17). This chapter specifically addresses their use as analgesics.

Analgesic action of tricyclic antidepressant (TCA) medications for neuropathic pain has been extensively studied. Secondary-amine TCAs, nortriptyline and desipramine, are preferred to tertiary-amine TCAs (e.g., amitriptyline) because they have been shown to be equally effective and have fewer side effects (e.g., drowsiness) (18,19). Another TCA, doxepin, has shown some efficacy as a topical analgesic in managing chronic neuropathic pain (20).

A relatively newer class of antidepressants, selective serotonin reuptake inhibitors (SSRIs), is hypothesized to affect brain stem pain-modulating systems. Initial interest in using this class of medication for analgesia developed from a few promising case reports. However, a major systematic review concluded that there is very limited evidence that SSRIs are effective for management of neuropathic pain and more studies are warranted to draw definitive conclusions (21).

The serotonin-norepinephrine reuptake inhibitors (SNRIs) appear to be replacing SSRIs for neuropathic pain conditions. Venlafaxine (Effexor) and duloxetine (Cymbalta) are two SNRIs that have been studied in the treatment of pain due to postherpetic neuralgia and diabetic neuropathy. Duloxetine is currently approved for the treatment of diabetic neuropathy and venlafaxine was found to be as effective as imipramine in treatment of polyneuropathy (22,23). The popularity of SNRIs is also vested in their cost effectiveness and favorable side-effect profiles (24).

Other antidepressants that have been studied as analgesics include several that do not fall into any one particular chemical class, including trazodone and bupropion. Both of these have received somewhat less attention than the previous three classes of antidepressants but deserve further comment. Additional antidepressants in this category include mirtazapine and nefazodone. Although 5 years have passed since the last publication of this book, there is still only one case report in the peer-reviewed literature on mirtazapine and one basic science study on nefazodone in the setting of pain (25,26).

Trazodone is chemically unrelated to other antidepressants. It is rarely used for depression but is more commonly used as a hypnotic. Although there is some literature on it as an analgesic, a review of 59 randomized placebo-controlled trials of antidepressants as analgesics concluded that trazodone is not effective (27,28).

A placebo-controlled crossover trial confirmed that bupropion SR (sustained release, 150 to 300 mg daily) is effective and well tolerated in treating neuropathic pain (29). In contrast, it was found to be ineffective in treating non-neuropathic, chronic pain (30).

### Mechanism of Action and Pharmacokinetics

TCAs increase aminergic transmission by inhibiting serotonin and norepinephrine (NE) reuptake to different

degrees at presynaptic nerve-ending terminals. For example, amitriptyline primarily inhibits serotonin reuptake whereas nortriptyline primarily inhibits NE reuptake. As a result, TCAs elevate pain thresholds in depressed and nondepressed patients. Analgesic doses are usually lower than those for primary depression. These agents are rapidly absorbed and bind avidly to plasma albumin. Metabolism first involves demethylation of tertiary amine to secondary amine, followed by hydroxylation, glucuronidation, and eventual renal excretion as inactive metabolites.

SSRIs selectively inhibit serotonin reuptake, with less of an effect on NE reuptake. This selectivity offers the advantage of a superior side-effect profile. End results include prolonged decreased production of serotonin and down-regulation of presynaptic and postsynaptic receptors. Paroxetine and sertraline are the most frequently used agents in this class and both have a chemical structure that is unique among the SSRIs as well as other antidepressants. As a whole, this class is well absorbed orally and then undergoes hepatic metabolism followed by renal excretion.

Bupropion's mechanism of action is still uncertain but evidence suggests that it inhibits dopamine (DA) and NE reuptake; its effect is greater on the former than on the latter (31). Bupropion is hepatically metabolized into an active metabolite, 4-hydroxybupropion, which is excreted in the urine.

Trazodone possibly acts via serotonin reuptake inhibition and mixed serotonin agonist-antagonist effects. Although extensively metabolized in the liver, it has variable clearance that may lead to accumulation in some patients.

SNRIs act as NE reuptake inhibitors via  $\alpha_2$ -adrenergic receptor blockade, serotonin reuptake inhibitors, and it binds to opioid receptors. This combined mechanism of action is somewhat similar to that of tramadol.

### Preparations and Dosing

Dosage, side effects, and miscellaneous information about the most commonly used antidepressants for neuropathic and chronic pain are shown in Table 65-3.

### Relevant Side Effects and Drug Interactions

Antidepressants in general are associated with a high incidence of sexual dysfunction that is often underreported in the product literature (32). Antidepressants that inhibit serotonin reuptake (e.g., SSRIs, SNRIs, trazodone) can cause "serotonin syndrome," a hyperexcitable state of nervousness and insomnia.

TCA side effects are mainly anticholinergic and include dry mouth, blurred vision, tachycardia, constipation, aggravation of glaucoma, and urinary retention. They also cause antihistamine side effects such as sedation (therefore they are often prescribed as a single bedtime dose) and weight gain, related to an increased appetite for carbohydrates. TCAs also exert some quinidine-like cardiac effects, including atrioventricular (AV) conduction-time prolongation. Cognitive/behavioral alterations (e.g., agitation and memory impairment) appear at plasma TCA concentrations greater than 0.450  $\mu\text{g/mL}$  (33);

many TCAs, notably dothiepin, are fatal at concentrations greater than 1  $\mu\text{g/mL}$  (34). Nortriptyline is generally considered superior to all TCAs because it is more potent and has a comparatively wide therapeutic range (35). Elderly and otherwise medically fragile patients should probably be started on nortriptyline rather than amitriptyline for the above reason and because side effects such as orthostatic hypotension and significant morning sedation, which can potentially interfere with rehabilitation efforts in this patient population, are relatively less common.

Since SSRIs have a relatively specific effect on serotonin reuptake without a significant effect on NE reuptake, their side-effect profile is generally superior to TCAs—especially with respect to cardiovascular issues—and they are much safer in cases of overdose. However, abrupt cessation of SSRI has been reported to cause SSRI discontinuation syndrome in some individuals. This syndrome includes dizziness, light-headedness, insomnia, fatigue, anxiety/agitation, nausea, headache, and sensory disturbance.

Bupropion has caused seizures and interference with cardiac conduction (ventricular arrhythmias and third-degree heart block). Idiosyncratic reactions including Stevens-Johnson syndrome, rhabdomyolysis, and severe hepatotoxicity have also been reported (36–38). There is evidence that bupropion is a cytochrome P450–2D6 (CYP2D6) inhibitor, but the clinical significance of this has yet to be established (39). The sustained-release (SR) bupropion is generally better tolerated than the immediate-release (IR) form.

Trazodone can be quite sedating and possesses other mild anticholinergic effects, but these are less generally than those from TCAs. It also exhibits  $\alpha$ -adrenergic blocking properties, which can cause penile or clitoral priapism (40).

TCAs, SSRIs, and bupropion should not be used in patients taking monoamine oxidase inhibitors (MAOIs) and should be instituted cautiously in patients who have been off of MAOIs for at least 2 weeks. The only exception to this rule is nortriptyline, which can be safely combined with MAOIs or sertraline (an SSRI) (35). Concomitant use of other TCAs or any of SSRIs and MAOIs can cause hyperpyretic crises, seizures, and death. TCAs should also be used cautiously in patients taking other anticholinergic medications, neuroleptics, or central nervous system (CNS) depressants.

It is not known whether interactions occur between trazodone and MAOIs. Trazodone may increase serum digoxin and phenytoin levels and can cause either an increase or a decrease in prothrombin times (PTs) in patients on warfarin (41).

Venlafaxine's most common side effects are from increased serotonin levels (irritability, insomnia, and sexual dysfunction) and also include constipation and nausea. There are several case reports of false-positive phencyclidine (PCP) results from ingesting high dosage of venlafaxine (42,43).

### Corticosteroids

#### Relevance to Psychiatry

Anti-inflammatory effects of corticosteroids are usually more important to the psychiatrist than their mineralocorticoid and

**TABLE 65.3 Antidepressants Used in the Treatment of Neuropathic Pain<sup>a</sup>**

Generic Name	Dose (mg) Neuropathic Pain and (Depression)	Miscellaneous
<b>[TCAs]</b>		
Amitriptyline (Elavil/Saroten/Endep/Vanatrip)	10–100 @ H/S (150–300/d); begin @ 12.5–25 qH/S, and titrated as tolerated	Dry mouth and sedation very common Demethylated to nortriptyline
Nortriptyline (Aventyl, Pamelor)	10–30 @ H/S (50–150/d)	First metabolite of amitriptyline; less side effects but not as potent
Doxepin (Sinequan) topical	Topical application of 3.3% doxepin, 0.025% capsaicin, and 3.3% doxepin/0.025% capsaicin produces analgesia of similar magnitude. The combination produces more rapid analgesia. Cream: 50 mg/g	Minor side effects
Desipramine (Norpramin)	Start 25–100 PO once daily or in divided doses, increase to effective dose of 100–200 mg/d, MAX 300 mg/d (111 mg) used in studies	<ul style="list-style-type: none"> <li>Cardiovascular: decreases of BP on rising from a sitting or a lying position, which may cause dizziness or fainting; increases of BP, rapid HR, pounding heart, altered heart rhythm</li> <li>Nervous system: sedation, confusion, nervousness, restlessness, sleep difficulties, numbness, tingling sensations, tremors, increased seizure tendency</li> <li>Autonomic: blurred vision, dry mouth, decreased sweating, difficulty urinating, constipation.</li> <li>Skin: rashes, sensitivity to sunlight</li> <li>Body as a whole: weight gain</li> </ul>
Imipramine (Tofranil)	Start 75 mg PO qhs. Increase to 150 mg PO qhs or in divided doses	Dry mouth, constipation, urinary retention, increased HR, sedation, irritability, dizziness, and decreased coordination
<b>[SSRIs]</b>		
Citalopram (Celexa)	20–40 qd (20–60 qd)	Relatively short half-life
Fluoxetine (Prozac)	20 qd (20–80 qd)	Very popular when first released; blamed in the press as a contributing factor to several high-profile murders
(Prozac Weekly)	90 qw of Prozac Qwk	
(Sarafem)	20–40 qd (20–60 qd) throughout menstrual cycle or 14 prior to menses	
Fluvoxamine (Luvox)	100 qd (50–150 bid)	Least studied of the SSRIs for pain
Paroxetine (Paxil) (Pexeva)	20–50 qd (20–50 qd)	Most selective of the SSRIs
(Paxil CR)	25 mg PO qam max 62.5 mg/d	
Sertraline (Zoloft)	50–150 qd (50–200 qd)	Tablets and oral concentrate; serotonin syndrome (hyperserotonergic state) with tramadol coadministration; also used for obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD)
<b>[Other antidepressants]</b>		
Bupropion SR (Wellbutrin SR)	150–300 qd (100–450 qd)	SR formulation have a better side-effect profile vs. IR preparation, esp. for sexual dysfunction and seizures; also used for smoking cessation (Zyban)
Wellbutrin, Zyban, Buproban	Start 100 mg PO bid IR tab increase to tid	
Wellbutrin XL	150–300 qd (100–450 qd)	
Trazodone (Desyrel)	Start 50–150 mg/d PO in divided doses; @ H/S (200–300 bid), usual effective dose is 400–600 mg/d	Priapism that can be severe; less anticholinergic side effects vs. TCAs

(continued)

**TABLE 65.3 Antidepressants Used in the Treatment of Neuropathic Pain<sup>a</sup> (Continued)**

Generic Name	Dose (mg) Neuropathic Pain and (Depression)	Miscellaneous
Mirtazapine (Remeron)	Initial dose 15 mg taken at bedtime. The dose may be increased in 15-mg increments every 1 or 2 wk as needed. Typical doses range between 15 and 45 mg. Dosages above 45 mg/d are not recommended	Side effects are sleepiness and nausea. Other common side effects are dizziness, increased appetite, and weight gain. Less common adverse effects include weakness and muscle aches, flu-like symptoms, low blood-cell counts, high cholesterol, back pain, chest pain, rapid heartbeats, dry mouth, constipation, water retention, difficulty sleeping, nightmares, abnormal thoughts, vision disturbances, ringing in the ears, abnormal taste in the mouth, tremor, confusion, upset stomach, and increased urination
Remeron SolTab Nefazodone (Serzone)	50-, 100-, 150-, 200-, and 250-mg tablets. Initial dose of nefazodone is 100 mg taken by mouth twice daily. The dose may be increased in 100 or 200 mg increments once a week. Most commonly, final dosages range between 300 and 600 mg taken by mouth each day	Side effects: dizziness, difficulty sleeping, weakness, or agitation. Other common adverse effects are sleepiness, dry mouth, nausea, constipation, blurred vision, and confusion
[Antidepressants]SNRIs Venlafaxine (Effexor)	18.75–75 qd, divided bid or tid (37.5–75 divided bid or tid) 75 mg/d divided bid-tid MAX 375 mg/d 25, 37.5, 50, 75, 100	An extended-release form (Effexor XR) is used for depression but not studied yet for pain
(Effexor XR)	(37.5–75 mg PO daily) MAX 225 mg/d Tabs-37.5, 75, 150	
Duloxetine (Cymbalta)	Total dose of 40 mg/d (given as 20 mg bid) to 60 mg/d (given either once a day or as 30 mg bid), no evidence that doses >60 mg/d confer any additional benefits	Side effects: impaired thinking or reactions. Be careful if you drive or do anything that requires you to be awake and alert

<sup>a</sup>Note: Only those generally considered used for neuropathic pain are shown in the table.

androgenic/estrogenic effects. Psychiatrists today are using corticosteroids for a range of injection procedures, including fluoroscopic-guided spinal injection procedures and peripheral joint injection procedures. They are also prescribing them in either short, tapering oral courses (e.g., Medrol Dosepak) for patients with radiculopathy and other localized musculoskeletal conditions; or chronically for systemic inflammatory diseases. Besides their oral and injectable forms, corticosteroids can additionally be delivered transdermally by iontophoresis or phonophoresis.

### Mechanism of Action and Pharmacokinetics

Corticosteroids bind to receptors within a target cell's nucleus and cause an alteration in protein synthesis. These altered proteins then exert various mineralocorticoid, androgenic/estrogenic, and glucocorticosteroid effects. Corticosteroids are classified into one of these three categories depending upon their predominant effect. The focus of this section is the glucocorticosteroid class. At physiologic, but not pharmacologic, doses, glucocorticosteroid exerts

anti-inflammatory and immunosuppressive effects via the following mechanisms:

1. Inhibition of prostaglandin and leukotriene synthesis (research suggests that this occurs by preventing arachidonic acid release from phospholipids; this contrasts with NSAIDs and COX-II inhibitors, both of which act at a later step in prostaglandin synthesis via inhibition of COX isoenzymes)
2. Inhibition of chemotactic factor release, leading to a diminished attraction of white blood cells (WBCs) to sites of inflammation
3. Decrease in circulating lymphocytes and monocytes
4. Reduction of vascular permeability by acting as vasoconstrictors or by inhibiting vasodilator release (e.g., histamines and kinins)
5. Stabilization of lysosomal membranes (occurs only at higher steroid doses)

Oral glucocorticoids are hepatically metabolized and renally excreted at a rate proportional to the particular agent's water solubility. Hence, longer-acting glucocorticoids are less water soluble.

**TABLE 65.4** Corticosteroid Preparations

Corticosteroid Generic (Trade) Name	Route	Equiv. Oral Dose (mg)	Relative Potencies:		Duration
			Antiinflammatory (Mineralocorticoid)	Onset	
Betamethasone (Celestone)	PO/IM	0.6–0.75	20–30 (0)	Very fast	Long
Cortisone (Cortone)	PO	25	0.8 (2)		Short
Dexamethasone (Decadron, Decadron-LA)	PO/IM/IV	0.75	20–30 (0)	Fast, slow (LA)	Long
Hydrocortisone (Cortef, Solu-Cortef, Hydrocortone)	PO/IM/IV	20	1 (2)	Moderate (Cortef), fast (Solu-Cortef), slow (Hydrocortone)	Short
Methylprednisolone (Medrol, Medrol Dosepak, SoluMedrol)	PO/IM/IV	4	5 (0)	Slow	Intermediate
Prednisolone (Hydeltra)	PO/IM/IV	5	4 (1)	Moderate	Intermediate
Prednisone (Deltasone, Orasone)	PO	5	4 (1)	Fast	Intermediate
Triamcinolone (Aristocort, Kenacort, Kenalog)	PO/IM	4	5 (0)	Slow	Intermediate

**Preparations and Dosing**

The two most commonly used oral steroid preparations in many psychiatric practices are prednisone and methylprednisolone. The latter is often prescribed as Medrol Dosepak of 4-mg tabs, which provides an initial 24 mg of Medrol (equivalent to 30 mg of prednisone) and tapers to 0 mg over 7 days. The popularity of Dosepak comes from the fact that patients' instructions are conveniently printed on the package and it eliminates the need for patients to count out a different set of pills each day. Potential drawbacks to Medrol Dosepak are its higher expense compared to generic prednisone and a limited peak dose of merely 30-mg

prednisone. Some physicians overcome the low peak dose by prescribing two Medrol Dosepak to be taken simultaneously.

Corticosteroid selection can be made on the basis of equivalent cortisone dose, relative anti-inflammatory potency, relative mineralocorticoid potency, and onset and duration of action (44,45) (Table 65-4). For comparison, physiologic steroid doses are equivalent to 30 mg/day of hydrocortisone (7.5 mg/day of prednisone), whereas stress doses are equivalent to 300 mg/day of hydrocortisone (75 mg/day of prednisone). General dosing guidelines have also been developed (see Tables 65-4 and 65-5), but recent popularity of injectable

**TABLE 65.5** Corticosteroid Dosing Guidelines

- Use these only after less toxic therapy has been ineffective or is not an alternative
- Use the smallest corticosteroid amount that can control symptoms
- Administer the corticosteroid locally rather than systemically whenever possible
- Short-term use: Dosing qd (preferably in the a.m.) is more convenient and causes less adrenal suppression than qid dosing at quarter the total dose
- Chronic use: Dosing qod is less likely to suppress adrenal function
- Do not use the term *steroids* because of this word's negative connotations. Although the terms *cortisone* and *prednisone* may also have negative connotations, explain that osteoporosis and truncal obesity only occur with chronic use
- Forewarn patients that oral steroids typically cause a metallic taste
- Adrenal suppression is likely for dose, potency, and duration as follows:  
Doses  $\geq 100$  mg hydrocortisone (25 mg prednisone) daily  $\times 3$  d  
Doses  $\geq 30$  mg hydrocortisone (7.5 mg prednisone) daily  $\times 30$  d
- Wean patients off over weeks or months if taking steroids for more than several weeks
- If unsure that patient has become adrenally suppressed, refer to endocrinologist for metyrapone or insulin-tolerance testing. Recovery of adrenal function is variable
- For corticosteroid injections:  
Can decrease chance of corticosteroid arthropathy with limit of: 3/y; 20/lifetime  
Never inject directly into a tendon and avoid weight-bearing peritendinous injections (e.g., Achilles, patellar, posterior tibial) or risk tendon rupture

corticosteroids has raised concern that there is a lack of uniform guidelines for treating intra-articular joint conditions (46,47).

### Relevant Side Effects and Drug Interactions

Most side effects occur after prolonged administration and many are simply manifestations of Cushing's syndrome as shown in Table 65-6. Among these conditions, steroid myopathy and avascular necrosis are particularly pertinent to physiatry. The first, necrosis of the femoral or humeral head, is a rare idiosyncratic event that can occur after a short course of prednisone. Physiatrists who routinely perform electrodiagnostic studies are likely to be familiar with the need to "rule out steroid myopathy."

Skin depigmentation and subcutaneous atrophy are dermatological complications that can occur with corticosteroid injections but can be minimized by adding local anesthetic or normal saline vehicle into the injectate and flushing the needle of residual corticosteroid with saline or local anesthetic injection before removal from the skin. Skin changes from chronic oral corticosteroids can lead to pressure ulcers and easy bruising.

Acceleration of corticosteroid metabolism occurs with medications that induce hepatic microsomal enzymes, especially phenobarbital, phenytoin, carbamazepine, and rifampin. In contrast, corticosteroid potency is increased by NSAIDs and exogenous estrogens (47). Clinicians should consider discontinuing NSAIDs or switching to a COX-II inhibitor if concomitant corticosteroid use is needed as corticosteroids are risk factors for NSAID-induced GI bleeding.

Lastly, although not a true side effect, a potential problem with corticosteroids is that they mask forewarning inflammation of various disorders. Thus, there is a tendency for patients to overvalue temporary relief and ignore the underlying disorder. An example is a patient who has received a subacromial steroid injection and soon resumes repetitive overhead activities that initially led to impingement.

**TABLE 65.6 Corticosteroid Side Effects**

Organ System	Side Effect
Central nervous system	Behavior and mood alteration
Cardiovascular	Fluid retention; HTN
Endocrine/metabolism	Adrenal atrophy; amenorrhea; appetite increase; glucose tolerance impairment; hypernatremia and hypokalemia; weight gain leading to "moon facies"
Gastrointestinal	Aggravation of peptic ulcer disease
Musculoskeletal	Avascular necrosis; bone demineralization; steroid myopathy
Skin	Acne, depigmentation, and subcutaneous atrophy with injection, fatty deposition leading to "buffalo hump", hirsutism, skin thinning

## Membrane-Stabilizing Medications: Antiarrhythmics

### Relevance to Physiatry

There are three circumstances under which a physiatrist might prescribe antiarrhythmics: first, in the inpatient rehabilitation setting, for patient who needs ongoing treatment for existing cardiac conditions; second, for a patient with neuropathic pain who responds to off-label use of type I antiarrhythmics (i.e., mexiletine, tocainide, lidocaine, and phenytoin); third, for a patient with myotonia-associated pain from certain neuromuscular disorders. Intravenous (IV) lidocaine, as an analgesic agent, is not discussed in detail in this chapter because it is infrequently used other than as a predictive test for mexiletine treatment in highly specialized pain management clinics (48). In contrast, the low sensitivity of IV lidocaine infusion renders the test inappropriate for definitive diagnosis of neuropathic pain (49).

Literature pertaining to oral antiarrhythmics for neuropathic pain is still limited to mexiletine because other oral analogues (e.g., flecainide and tocainide) have some potentially lethal adverse effects (50). It is noteworthy that, prior to tocainide's withdrawal from U.S. market over safety concerns, there were successful reports on using the agent as treatment for myotonic pain in paramyotonia congenita and Thomsen-Becker myotonia (51).

Earlier case reports and prospective studies suggested that mexiletine is efficacious and safe in various neuropathic pain states including pain from peripheral nerve damage, diabetic neuropathy, alcoholic neuropathy, phantom limb pain, multiple sclerosis complicated by painful dysesthesias, and thalamic pain syndrome (50,52–57). A 2005 systematic review of local anesthetics found mexiletine (at a median dose of 600 mg/day) to be "superior to placebo in relieving neuropathic pain and... as effective as other analgesics used for this condition" (58). Critics, nonetheless, persist to this day because most studies were of relatively short duration and fewer than 400 patients have been studied altogether (59).

### Mechanism of Action and Pharmacokinetics

Type I antiarrhythmics (e.g., lidocaine, mexiletine, and tocainide) block Na<sup>+</sup> channels in nerve and muscle cell membranes with a subsequent reduction in the number of abnormal ectopic impulse generated by dysfunctional peripheral nerves. Lidocaine and oral analogues differ in that the latter have low first-pass metabolism, which enhances their oral bioavailability.

### Preparations and Dosing

Mexiletine is available in 150-, 200-, and 250-mg caplets. Neuropathic pain doses are lower (150 to 300 mg tid) than those used for arrhythmias (200 to 400 mg tid). It can be initiated as a 150-mg-per-day regimen, titrated weekly.

### Relevant Side Effects and Drug Interactions

Mexiletine's potential side effects are acute in onset and can involve the GI, neurologic, and cardiovascular systems. One mexiletine study of experimentally induced pain found that

analgesic dosing caused side effects at an average of 993 mg/day, whereas another study found negligible side effects at doses up to 900 mg/day (60). GI side effects include nausea, anorexia, and gastric irritation in up to 40% of patients. Another 10% of patients experience neurologic side effects similar to those of other class I antiarrhythmics, including dizziness, visual disturbances, anxiety in patients with history of anxiety disorder, tremor, and altered coordination. Individuals with abnormal cardiac conduction are also at risk of mexiletine-induced exacerbation; mexiletine is absolutely contraindicated in second- and third-degree heart block uncontrolled by a pacemaker. Patients in fact should obtain an electrocardiogram (ECG) prior to starting this medication.

Mexiletine's pharmacologic disposition is susceptible to multiple alterations. For example, opioid analgesics, atropine, and antacids slow its absorption while metoclopramide enhances it. Phenytoin, rifampin, and smoking increase its metabolism. Mexiletine, in turn, may significantly reduce the clearance of theophylline and caffeine (61).

## Membrane-Stabilizing Medications: Anticonvulsants

### Relevance to Psychiatry

When anticonvulsants are used to treat neuropathic pain, they are generally referred to as *membrane-stabilizing medications*. Their initial use as antineuralgic drugs in the 1960s was derived merely from positive clinical observations. Current research efforts are dedicated to understanding this phenomenon. A popular theory now attributes similarities between neuropathic pain and epilepsy pathophysiology models to the efficacy of anticonvulsants in treating both conditions (62). As supportive evidence continues to accumulate, anticonvulsants have marked a new era in the treatment of pain.

Various anticonvulsants have yielded good results thus far and pregabalin is the latest addition to the list. Specific drugs will be discussed individually as there are some significant differences among them with respect to side effects and mechanisms of action (Tables 65-7 and 65-8).

### Gabapentin (Neurontin)

#### Relevance to Psychiatry

Gabapentin is still among the first-line treatments for neuropathic pain. It has been shown to be as effective as TCAs and carbamazepine and has a highly favorable side-effect profile and reputation for minimal drug interactions (63). Although evidence is lacking for its efficacy in acute pain states (64), there is now growing evidence supporting its efficacy in treating painful diabetic neuropathy (65–68). It has also been investigated for spasticity reduction in spinal cord injury (SCI) patients (69,70).

#### Mechanism of Action and Pharmacokinetics

See Tables 65-7 and 65-8.

Gabapentin's mechanism of action is still poorly understood. It was originally thought to inhibit gamma-aminobutyric

acid (GABA) receptors because of its structural similarity to GABA, a major CNS excitatory neurotransmitter. While there is evidence suggesting that it does indeed interact with pre-synaptic GABA-B receptors to reduce glutamate release, other studies point to more possibilities. Specifically, gabapentin has been implicated as a calcium channel blocker (CaCB) and hippocampal CA1 neural enhancer. There is also evidence that it may raise the interneuron pool excitability threshold of polysynaptic reflexes (71).

Gabapentin is transported from the GI tract into the bloodstream by the amino acid transport system. It does not bind to plasma protein, is not metabolized, and is ultimately excreted by the kidneys at the rate of creatinine clearance.

### Preparations and Dosing

The reported dosage that provides adequate relief from neuropathic pain ranges from 900 to 2,400 mg per day, divided tid. When initiating therapy, a 300-mg dose at bedtime on the first day, then bid dosing on the second day, and tid dosing thereafter can be used as a way of helping patients accommodate to its CNS depressive effects. A maximum of 3,600-mg daily dose has been well tolerated in a small number of patients for short duration.

### Relevant Side Effects and Drug Interactions

CNS depression (e.g., somnolence, dizziness, ataxia, and fatigue) is the main side effect. Nystagmus has also been reported. Side effects are generally transient with resolution in 2 weeks. There have been only rare reports of adverse events (e.g., rash, leukopenia, increased blood urea nitrogen (BUN), thrombocytopenia, and nonlethal ECG abnormalities) that required its discontinuation. Given the rarity of serious adverse events, routine laboratory monitoring and monitoring of serum gabapentin levels are not indicated.

There are two documented drug interactions, but both are deemed to be clinically insignificant. Cimetidine minimally decreases renal gabapentin excretion, and Maalox reduces gabapentin's bioavailability by 20%. This lack of significant drug interactions is expected given its pharmacokinetics profile.

### Carbamazepine (Tegretol)

#### Relevance to Psychiatry

Carbamazepine was the first anticonvulsant to be studied in neuropathic pain clinical trials. Results from these trials confirmed its indication in treating trigeminal neuralgia (Food and Drug Administration [FDA] approved), glossopharyngeal neuralgia, painful diabetic neuropathy, and postherpetic neuralgia. It has not been as extensively studied in other neuropathic conditions. Traditional belief is that carbamazepine is especially effective for neuropathic pain that is acute and lancinating, as is often found in postamputation neuroma. Its relative lack of CNS side effects compared to other anticonvulsants offers an obvious advantage with respect to functional activities. The unfortunate combination of potential hematologic toxicity, the need for periodic blood work, baseline and periodic eye examinations, and numerous medication interactions renders carbamazepine a less attractive choice.

**TABLE 65.7 Anticonvulsant Efficacy and Pharmacokinetics in Neuropathic Pain**

Efficacy	Medication	Specific Neuropathic Pain Uses	Pharmacokinetics
Efficacious	Gabapentin (Neurontin)	Especially diabetic neuropathy and postherpetic neuralgia (FDA approved)	Not protein bound or metabolized; renal excretion
	Carbamazepine (Tegretol)	Trigeminal neuralgia (FDA-approved), glossopharyngeal neuralgia, painful diabetic neuropathy, and postherpetic neuralgia	Binds and prolongs inactivation of voltage-dependent sodium channels. The number of action potentials is consequently decreased. Highly plasma protein-bound, variable $t_{1/2}$ as it induces its own metabolism
	Pregabalin (Lyrica)	FDA approved in treating diabetic neuropathy pain, postherpetic neuralgia pain. Used off-label for other neuropathic pain conditions. Mounting evidence it can manage pain due to fibromyalgia	Does not bind to plasma proteins and nearly the entire dose is excreted unchanged in the urine, with elimination following first-order kinetics
Unclear	Clonazepam (Klonopin)	Some efficacy in trigeminal neuralgia	Good absorption; highly plasma protein-bound, lipid soluble, and hepatically metabolized
	Lamotrigine (Lamictal)	Primarily indicated in treatment for epilepsy and bipolar disorder. Provides minimal, if any, therapeutic effects in acute and chronic pain. Some efficacy in trigeminal neuralgia; peripheral neuropathy poststroke syndromes	Good oral absorption; hepatic conjugation; renal excretion
	Oxcarbazepine (Trileptal)	Efficacy in newly diagnosed and refractory trigeminal neuralgia and possible merit in areas of neuropathic pain and bipolar disorder other neuropathic pain conditions	Hepatically metabolized to its active metabolite; renal excretion
	Phenobarbital (Solfoton)	No clinical studies in humans in peer-reviewed literature	Moderate protein binding; hepatic metabolism; pH-dependent renal excretion
	Phenytoin (Dilantin)	Conflicting results in trigeminal neuralgia and diabetic neuropathy	Metabolism saturable at high plasma levels, thus large concentration increases from additional small doses
	Tiagabine (Gabitril)	Two small trials showed beneficial outcome in painful sensory neuropathy	Highly protein bound; at least 2 metabolic pathways
	Topiramate (Topamax)	Conflicting results in studies of neuropathic pain and diabetic neuropathy. Some evidence in refractory intercostal neuralgia, trigeminal neuralgia, and trigeminal autonomic cephalgias	Rapidly absorbed orally, a third of the drug is metabolized by the hepatic CYP450 system into inactive metabolites, remainder excreted renally unchanged
	Valproate (valproic acid, Depakene)	Efficacy in neuropathic cancer pain but not paraplegia central pain. Mixed results in neuropathic pain, postherpetic neuralgia, and polyneuropathy	A lipid-soluble compound, rapidly absorbed and becomes tightly protein bound. Metabolized in the liver through oxidation and glucuronidation pathways. Active metabolites and a small, unchanged portion are renally eliminated.
	Zonisamide (Zonegran)	Studies in neuropathic pain are lacking	Renally excreted intact and as a glucuronide metabolite

***Mechanism of Action and Pharmacokinetics***

See Tables 65-7 and 65-8.

Carbamazepine binds and prolongs inactivation of voltage-dependent sodium channels. The number of action potentials is consequently decreased.

Because of its high lipid solubility, it is slowly absorbed into the body following oral administration and becomes highly protein bound. It induces the hepatic CYP450 enzymes and this increases the metabolism of multiple medications—including its own.

**TABLE 65.8** Proposed Mechanism of Action of Anticonvulsants in Neuropathic Pain

Proposed Mechanism	Medications
Na <sup>+</sup> channel blocker	Carbamazepine; lamotrigine; oxcarbazepine; phenytoin; valproate; zonisamide
Ca <sup>++</sup> channel blocker	Gabapentin; oxcarbazepine; zonisamide
GABA receptor activity	Barbiturates; BNZs
GABA metabolism	Gabapentin; tiagabine; valproate
Glutamate receptor activity	Carbamazepine; lamotrigine; topiramate
Glutamate metabolism	Gabapentin

**Preparations and Dosing**

Carbamazepine is available in tablets, chewable tablets, extended-release capsules, syrup, suspensions, and rectal suppositories preparations. Although there are no dosing guidelines for trigeminal neuralgia, it is commonly used to treat this condition with 100 mg bid initially, and then the dose is gradually increased to a maximum of 400 mg tid. Given the potential for hematologic toxicity, the maintenance dose should be reduced to the minimum effective level. The extended-release form, Tegretol-XR, can be given bid to achieve the same total daily doses as described above.

**Relevant Side Effects and Drug Interactions**

Severe toxicity can occur with carbamazepine including leukopenia and thrombocytopenia, aplastic anemia and

agranulocytosis (rare), hepatotoxicity, skin reactions (e.g., Stevens-Johnson syndrome and toxic epidermal necrolysis), and (72), to a lesser degree, renal dysfunction. Prior to initiating carbamazepine, a complete blood count (CBC), liver function tests (LFTs), BUN and urinalysis, reticulocyte count, and serum iron levels are recommended. CBC and LFTs should be reviewed periodically and, if toxicity is suspected, consideration should be given for medication discontinuation.

Due to the pharmacokinetics described previously, carbamazepine interacts with many medications (Table 65-9). In addition, it should not be given to individuals with TCA hypersensitivity due to potential crossreactivity, nor should it be used within 2 weeks of an MAOI.

**Clonazepam (Klonopin)****Relevance to Physiatry**

This benzodiazepine (BNZ) has been used to provide relief in neuropathic pain states (especially in patients with trigeminal neuralgia who are either intolerant to or have failed carbamazepine, baclofen, or phenytoin) and movement disorders (e.g., sleep-related nocturnal myoclonus, restless legs syndrome, tar dive dyskinesia, phantom limb pain, and opioid-related myoclonic jerks).

**Mechanism of Action and Pharmacokinetics**

See Tables 65-7 and 65-8.

Clonazepam is avidly bound to plasma protein and is highly lipid soluble. It is acetylated into nonactive metabolites in the liver and is gradually excreted by the kidneys. Low level of metabolites is also excreted in breast milk. In spite of this, there have not been reports of adverse outcome in newborns; lactation is therefore not a contraindication (73).

**TABLE 65.9** Potential Drug-Drug Interactions with Carbamazepine

Interaction	Decreased Serum Level	Increased Serum Level
Medications whose serum levels are affected by carbamazepine	Acetaminophen, alprazolam, amitriptyline, bupropion, busprione, citalopram, clobazam, clonazepam, clozapine, cyclosporine, delavirdine, desipramine, diazepam, dicumarol, doxycycline, ethosuximide, felbamate, felodipine, glucocorticosteroids, haloperidol, itraconazole, lamotrigine, levothyroxine, lorazepam, methadone, midazolam, mirtazapine, nortriptyline, olanzapine oral and other hormonal contraceptives, oxcarbazepine, phenytoin, praziquantel, protease inhibitors, quetiapine, risperidone, theophylline, tiagabine, topiramate, tramadol, triazolam, trazodone, valproate, warfarin, ziprasidone, zonisamide	Clomipramine, phenytoin, primidone
Medications that affect serum carbamazepine levels	Cisplatin, doxorubicin HCL, felbamate, methsuximide, phenobarbital, phenytoin, primidone, rifampin, theophylline	Acetazolamide, azole antifungals, CaCBs, cimetidine, clarithromycin, dalfopristin, danazol, delavirdine, diltiazem, erythromycin, fluoxetine, fluvoxamine, grapefruit juice, isoniazid, itraconazole, ketoconazole, loratadine, nefazadone, niacinamide, nicotinamide, protease inhibitors, propoxyphene, quinine, quinupristin, troleandomycin, valproate, verapamil, zileuton

**Preparations and Dosing**

Clonazepam is available as 0.5-mg, 1-mg, and 2-mg tablets. These tablets distinguish themselves with a unique K-shaped perforation in the middle of the pill. For movement disorders, clonazepam is begun at either 0.5 mg at bedtime or 0.5 mg tid, and it can be titrated up to 2 mg tid. A daily dose of 0.5 to 1.0 mg is recommended to treat trigeminal neuralgia (74).

**Relevant Side Effects and Drug Interactions**

Ataxia and personality changes can develop early in the treatment course but may subside with long-term use. At the other end of the spectrum, withdrawal often causes a flu-like syndrome, and abrupt discontinuation of a chronic, high-dose regimen can even lead to seizures. Moreover, common to all BNZs, chronic clonazepam use can result in psychological addiction and physical tolerance. Caution should be exercised when clonazepam is given along with another CNS depressant.

**Lamotrigine (Lamictal, Lamictal CD)****Relevance to Psychiatry**

Lamotrigine is primarily indicated in treatment for epilepsy and bipolar disorder. Multiple, well-designed clinical trials have investigated its efficacy in neuropathic pain, but a recent systematic review concluded that lamotrigine provides minimal, if any, therapeutic effects in acute and chronic pain (75). In addition, fatal skin reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported.

**Oxcarbazepine (Trileptal)****Relevance to Psychiatry**

Oxcarbazepine is a structural analog of carbamazepine. It has been used in the treatment of epilepsy since 1990. There is convincing evidence of its efficacy in newly diagnosed and refractory trigeminal neuralgia (76). In addition, it has emerging merit in areas of neuropathic pain and bipolar disorder (77).

**Mechanism of Action and Pharmacokinetics**

See Tables 65-7 and 65-8.

Liver microsomes metabolize oxcarbazepine into an active metabolite, 10-monohydroxy metabolite (MHD), which exerts the desired pharmacologic effects. This process minimally induces hepatic CYP450 enzymes. MHD is excreted by the kidneys.

**Preparations and Dosing**

Oxcarbazepine is available as 150-, 300-, and 600-mg scored tablets; and as a 60 mg/mL suspension. Rapid titration (over 7 to 10 days) from the initial dose (ranging from 75 to 300 mg bid) to a maximum of 1,200 mg bid is recommended. Therapeutic range for trigeminal neuralgia extends from 600 to 1,800 mg per day.

**Relevant Side Effects and Drug Interactions**

Although a carbamazepine analogue, oxcarbazepine is not associated with serious hematologic toxicity. CNS and GI disturbances are instead reported; between 20% and 25% of patients discontinue oxcarbazepine due to its side effects.

The coadministration of felodipine with CaCBs and/or oral contraceptives should be avoided. The specific mechanism is undetermined, but verapamil (a CaCB) is known to decrease oxcarbazepine concentration by 20% and oxcarbazepine, in turn, decreases CaCB felodipine concentration by 30%. As for contraceptives, oxcarbazepine stimulates their metabolism and, in effect, diminishes their efficacy (78). Antiepileptic drug (AED) coadministration, a regular practice in the setting of epilepsy but not neuropathic pain, also warrants caution because CYP450 enzymes inducers (e.g., carbamazepine, phenobarbital, and phenytoin) decrease mean plasma oxcarbazepine concentrations by 40%.

**Phenobarbital (Luminal, Solfoton)**

There is limited evidence for the effectiveness of phenobarbital in pain management (79). As is true of all barbiturates, human neuropathic pain studies are lacking and sedative properties limit their usage. Phenobarbital thus has a very limited role in neuropathic pain management.

**Phenytoin (Dilantin)****Relevance to Psychiatry**

Besides its well-known anticonvulsant use, phenytoin is also used off-label as a neuropathic pain agent. It was the first anticonvulsant used as an antinociceptive agent and was confirmed (via controlled clinical trials) to be effective in managing trigeminal neuralgia and diabetic neuropathy more than 20 years ago. Recent clinical trials have ironically shown conflicting evidence (80). In addition to this ambiguity, there is a significant potential for medication interactions. In contrast, phenytoin offers the advantage of relative low cost and once a day dosing.

**Mechanism of Action and Pharmacokinetics**

See Tables 65-7 and 65-8.

Oral absorption of phenytoin in the stomach is slow because it is weakly acidic. The drug is mainly bound to plasma proteins and it readily traverses the blood-brain barrier. Liver hydroxylates phenytoin into nonactive metabolites, which are excreted by the kidneys; this metabolic pathway is progressively saturated as the concentration of phenytoin increases.

**Preparations and Dosing**

Phenytoin is available as tablets, extended-release capsules, chewable tablets, injectable solution, and oral suspension. Neuropathic pain doses are often less than those used for seizures, but a specific therapeutic range has not yet been defined. Given the complex pharmacokinetics, it is important to monitor serum phenytoin levels because small increases in the dose can produce unexpectedly large increase in plasma concentrations.

**TABLE 65.10** Potential Phenytoin Drug Interactions

Can interfere with phenytoin absorption	Antacids (calcium-containing), Moban brand of molindone HCl
Can raise phenytoin levels	Alcohol (acute intake), amiodarone, chloramphenicol, chlordiazepoxide, diazepam, dicumarol, disulfiram, estrogens, ethosuximide, H <sub>2</sub> -antagonists halothane, isoniazid, methylphenidate, phenothiazines, phenylbutazone, phenylbutazone, salicylates, succinimide, sulfonamides, tolbutamide, trazodone
Can decrease phenytoin levels	Alcohol (chronic abuse), carbamazepine, reserpine, sucralfate
Can raise or decrease phenytoin levels (or its level can be raised or decreased by phenytoin)	Phenobarbital, sodium valproate, valproic acid
Efficacy is impaired by phenytoin	Corticosteroids, coumarin anticoagulants, digitoxin, doxycycline, estrogens, furosemide, oral contraceptives, quinidine, rifampin, theophylline, vitamin D

**Relevant Side Effects and Drug Interactions**

Side effects can be classified into three different categories: dose-related toxic effects, true side effects, and idiosyncratic reactions:

- *Toxic effects* generally occur between plasma levels of 20 and 40 µg/mL, but there is marked individual variation. The effects include sedation, ataxia, and nystagmus. Ingesting high doses over a prolonged period can result in painful peripheral neuropathy.
- *True side effects* from long-term use include hirsutism, osteomalacia, and hypocalcemia (secondary to interference with vitamin D metabolism), megaloblastic anemia (secondary to interference with vitamin B<sub>12</sub> metabolism), and gingival hyperplasia (secondary to interference with fibroblastic activity).
- *Idiosyncratic reactions* include blood dyscrasias and a rare clinical picture, which resembles malignant lymphoma.

Phenytoin should not be prescribed to pregnant women as there are conflicting reports on its teratogenic effects, including the fetal hydantoin syndrome. Cerebellar ataxia can occur at seizure management doses and may interfere with rehabilitation efforts.

Refer to Table 65-10 for drug interactions related to serum protein binding and hepatic metabolism.

**Pregabalin (Lyrica)****Relevance to Physiatry**

A second analogue of GABA, pregabalin, is FDA approved for use in treating diabetic neuropathy pain, postherpetic neuralgia pain, and epilepsy. It is also being used off label for other neuropathic pain conditions. Furthermore, there is mounting evidence that this potent “sibling” of gabapentin can help to manage pain due to fibromyalgia and symptoms of anxiety disorder (81–83).

**Mechanism of Action and Pharmacokinetics**

Based on its structure, pregabalin is expected to be a CaCB (84). However, it is also theorized to have other mechanisms of action, including modulating the release of various neurotransmitters

(i.e., glutamate, noradrenaline, and substance P [SP]) (85) to produce its net inhibitory effect on neurons.

Pregabalin has an oral bioavailability of greater than 90%. Concomitant food intake reduces the absorption rate but the total amount absorbed remains constant. Pregabalin does not bind to plasma proteins and nearly the entire dose is excreted unchanged in the urine, with elimination following first-order kinetics.

**Preparations and Dosing**

Pregabalin is available as capsules in the following strengths: 25, 50, 75, 100, 150, 200, 225, and 300 mg. For the treatment of painful diabetic neuropathy, it is generally started at 50 mg tid for 1 week then increased to a maximum of 1,000 mg tid. Therapeutic level of pregabalin for postherpetic neuralgia can be achieved with an initial dose of 75 mg bid or 50 mg tid, and increased to 150 mg bid or 100 mg tid after 1 week; the maximum dose for this purpose is 600 mg/day.

**Relevant Side Effects and Drug Interactions**

Dizziness, somnolence, and dry mouth have been frequently reported (86). Complaints of headache, weight gain, edema, blurred vision, and difficulty with concentration are also sometimes reported. Pregabalin is classified as a schedule V controlled substance because it leads to euphoria in selected individuals (87). As is true for gabapentin, pregabalin has no known drug interactions.

**Tiagabine (Gabitril)****Relevance to Physiatry**

Tiagabine became available at the turn of the century. Although it demonstrated antihyperalgesic and antinociceptive activity for neuropathic pain in animal models, placebo-controlled trial data are lacking; there are only two small clinical trials to date documenting its beneficial outcome (88–90). New research also proposes that tiagabine is indicated for Stiffman syndrome, bruxism, and tonic spasms in multiple sclerosis; however, more studies are needed to draw definite conclusions (91–93).

***Mechanism of Action and Pharmacokinetics***

See Tables 65-7 and 65-8.

Tiagabine is well absorbed orally; concomitant consumption of food decreases the absorption rate but the fraction absorbed remains constant. It is highly bound to plasma proteins. Metabolism of tiagabine involves oxidation and glucuronidation. Both pathways produce inactive metabolites, which are excreted by the biliary system (major) and the kidneys (minor).

***Preparations and Dosing***

Tiagabine is available in multiple strength tablets (2, 4, 12, 16, and 20 mg). Its neuropathic pain dosing schedule has not been established. The two published clinical trials investigated its efficacy in the range from 4 to 24 mg daily. When used as an anticonvulsant, however, it should be initiated at 4 mg every day, then increased to 8 mg at the beginning of week 2, and increased by 4 to 8 mg at weekly intervals thereafter, until clinical response is achieved or up to 32 mg/day.

***Relevant Side Effects and Drug Interactions***

Side effects are mild. CNS and GI disturbances (e.g., tiredness, somnolence, nausea, and abdominal pain) are the primary reasons that participants withdraw from tiagabine-related clinical trials. Tiagabine is also free of significant drug interactions.

***Topiramate (Topamax)******Relevance to Psychiatry***

Structurally derived from D-fructose, topiramate is FDA approved for seizure management and migraine prophylaxis, but is also used off-label for neuropathic pain and myoclonic jerks (94). Though several small studies support its efficacy in neuropathic pain, including diabetic neuropathy, larger studies have been disappointing (95,96). Minor studies also found that topiramate provides pain relief in refractory intercostal neuralgia, trigeminal neuralgia, and trigeminal autonomic cephalgias; these findings will likely invite additional future research (97,98). Other possible indications of less psychiatric relevance include obesity and bipolar disorder (99).

***Mechanism of Action and Pharmacokinetics***

See Tables 65-7 and 65-8.

Topiramate is rapidly absorbed into the body and does not bind well to plasma proteins (<20%). Only a third of the drug is metabolized by the hepatic CYP450 system into inactive metabolites. The remainder is excreted unchanged in the urine.

***Preparations and Dosing***

Topiramate is available as tablets (25, 50, 100, and 200 mg) and sprinkle capsules (15 and 25 mg). Its recommended daily dose as an adjunctive therapy for seizure prophylaxis is 200 mg bid and gradual titration from an initial daily dose of 25 mg over 8 weeks can reduce adverse cognitive effects. There are no dosing guidelines in neuropathic pain, but topiramate has been used between 200 and 400 mg per day.

***Relevant Side Effects and Drug Interactions***

Topiramate causes two general CNS-related side effects: delayed psychomotor actions (e.g., difficulty concentrating and sluggish speech) and somnolence. Weight loss (secondary to appetite suppression) and paresthesia can develop with chronic intake. The reversible effects discussed above are generally more common at seizure prophylaxis doses (100). Occasional cases of acute myopia and angle closure glaucoma have recently associated with topiramate use as well (101). Last but not least, animal models suggest that it may be teratogenic.

Topiramate is a carbonic anhydrase inhibitor; concomitant use with another carbonic anhydrase inhibitor should be avoided to prevent increased risk of renal stone formation. It also has a mild inductive effect on hepatic CYP450 enzymes and can hence increase metabolism of digoxin and oral contraceptive.

***Valproate (Valproic Acid, Depakene)******Relevance to Psychiatry***

Valproate has been used as a third-line agent for epilepsy and migraine prophylaxis. It is more recently being studied for use in neuropathic pain, postherpetic neuralgia, and polyneuropathy (102–106). Similar to several other anticonvulsants though, evidence of its efficacy is weak. Previously, it was the subject of a small randomized clinical trial in paraplegic central pain and was not effective (107). It has yielded variable results in experimentally induced central pain (108).

***Mechanism of Action and Pharmacokinetics***

See Tables 65-7 and 65-8.

Valproate, a lipid-soluble compound, is rapidly absorbed and becomes tightly protein bound. It is then metabolized in the liver through oxidation and glucuronidation pathways. Active metabolites and a small, unchanged portion are then renally eliminated.

***Preparations and Dosing***

Valproate is widely available in the following forms: caplet, sprinkle capsule, delayed-release tablet, extended-release tablet, syrup, and parenteral preparation. It is often initiated at 250 mg/day and is then titrated to a maximum dose of 1,000 mg bid.

***Side Effects and Drug Interactions***

Nausea, tremors, drowsiness, and weight gain are commonly encountered in the clinical setting. More serious complications include hepatotoxicity among the children population, pancreatitis, and prolonged bleeding time. Frequent monitoring of the previous parameters is recommended. Rare instances of valproate-induced encephalopathy are presumed to be caused by inhibition of ammonia metabolism (109). However, there are recent reports of encephalopathy in the absence of hyperammonia (110).

Valproate is an inhibitor of the oxidation and glucuronidation pathways; it inhibits the metabolism of phenytoin,

carbamazepine, and lamotrigine. It also decreases the clearance of amitriptyline and nortriptyline.

### **Zonisamide (Zonegran)**

#### ***Relevance to Psychiatry***

Zonisamide is FDA approved as an adjunctive therapy in partial seizures. A small, randomized clinical trial in 2005 concluded that it produces statistically insignificant effects when used in diabetic neuropathy (111). There has been renewed interest lately and at least one ongoing research dedicated zonisamide's analgesic mechanism in animal models (112).

#### ***Mechanism of Action and Pharmacokinetics***

See Tables 65-7 and 65-8.

#### ***Preparations and Dosing***

Zonisamide (100 mg) capsules are given daily for the first 2 weeks, after which the dose may be increased to 200 mg/day for at least 2 weeks. It can be increased to 300 and 400 mg per day, with the dose stable for at least 2 weeks to achieve steady state at each level. Evidence from controlled trials as an anticonvulsant suggests that 100 to 600 mg per day doses are effective, but there is no suggestion of increasing efficacy above 400 mg/day.

#### ***Relevant Side Effects and Drug Interactions***

Zonisamide is contraindicated in sulfonamide allergy. Rare cases of aplastic anemia and agranulocytosis have been reported. It can also cause adverse psychiatric CNS events (depression and psychosis), psychomotor slowing (concentration difficulties and speech/language problems, especially word-finding difficulties), and somnolence and fatigue. Concomitant phenytoin or carbamazepine use increases zonisamide clearance.

## **LOCAL ANESTHETICS—INJECTABLE ANESTHETICS**

### ***Relevance to Psychiatry***

In the outpatient psychiatric setting, injectable and sometimes topical anesthetics are frequently used to provide local anesthesia for a variety of procedures and as a diagnostic tool during intra-articular, soft tissue, and nerve block procedures. They can also be combined with corticosteroids in intra-articular and soft tissue injections to attain immediate pain relief. Injectable anesthetic can also be found as a component of proliferant solutions used in prolotherapy.

Local anesthetics are classified as esters (e.g., procaine) or amides (e.g., bupivacaine and lidocaine) based upon their chemical structure. Amide anesthetics are preferred over ester anesthetics because the latter are associated with a higher incidence of allergic reactions. Cross-sensitivity between the two classes does not occur (113). The amide class is further subdivided according to each drug's duration of action. Lidocaine, a short-acting injectable anesthetic, is commonly used in

percutaneous infiltration anesthesia. Long-acting injectable anesthetics (e.g., bupivacaine) are often reserved for procedures in which a longer degree of postprocedure pain relief is desirable. For example, after a positive lidocaine diagnostic shoulder impingement test, bupivacaine can be added to the corticosteroid to provide prolonged pain relief while corticosteroid gradually takes effect. This section will examine the amide anesthetics in greater detail.

### **Bupivacaine (Marcaine, Sensorcaine)**

Bupivacaine has been widely used for half a century now. Two comparable variants, levobupivacaine and ropivacaine, were subsequently introduced to circumvent the drawbacks of bupivacaine-related side effects, but bupivacaine remains a viable, inexpensive choice (114). Though spinal anesthesia for surgical procedures is considered to be the best indication for bupivacaine, a blend of bupivacaine and corticosteroid can also be injected as part of intra-articular, soft tissue, and some spinal injection procedures to provide long-term relief; candidates for this procedure are typically individuals who responded to prior lidocaine injection (115). Bupivacaine is also used as part of comparative local anesthetic medial branch blocks as a precursor to possible radiofrequency ablation, as is discussed in Chapter 68.

### **Lidocaine (Xylocaine)**

Lidocaine has been used as an anesthetic for over half a century. It has long replaced the first synthetic anesthetic, procaine, as the short-acting injectable anesthetic of choice because of its favorable side-effect profile. Lidocaine is regularly used in outpatient offices for procedures such as abscess drainage and laceration repair, but indications most relevant to psychiatry include regional anesthesia for musculoskeletal procedures and nerve blocks.

### **Mechanism of Action and Pharmacokinetics**

All amide anesthetics are speculated to be sodium channel blockers. They selectively inhibit tetrodotoxin-resistant sodium channels on dorsal root ganglia. These axonal structures are involved in generating nociceptive and temperature sensation. Local anesthetics cause a differential neural block—that is, sensory block with minimal loss of motor function (116,117).

Many factors influence an injectable anesthetic's activity including lipid solubility, level of ionization, molecular size, and vasodilation capacity that are proportional to its potency, onset, and duration of action. Amides undergo extensive hepatic metabolism to become active metabolites—whereas esters are hydrolyzed by plasma enzymes to para-aminobenzoic acid (a potential allergen). Serum levels peak between 5 and 25 minutes postinjection, depending on route of administration and rate of renal excretion.

### **Preparations and Dosing**

Table 65-11 summarizes the dosing guidelines for using lidocaine and bupivacaine in percutaneous infiltration anesthesia.

**TABLE 65.11** Commonly Used Local Anesthetics

Generic (Trade) Name	Applicable Preparations and Concentrations	Onset of Action (Duration)	Usual Dosage (mL): Bursal Injection (A); (IP); (Ish); (SA); (T) <sup>a</sup>	Usual Dosage (mL): Joint Injection Small (Large)	Dosage: Percutaneous Infiltration (Maximum Amount)
Bupivacaine (Marcaine, Sensorcaine)	0.25%, 0.5%, and 0.75%	5 min (2–4 h)	(A) 2½–4½; (IP) 4–4½ (Ish) 2½–4; (SA) 4–6; (T) 4½–9	1–2 mL (2–4 mL)	Up to 70 mL
Lidocaine (Xylocaine)	0.5%, 1%, 1.5%, and 2%	½–1 min (½ h)	(A) 2½–4½; (IP) 4–4½; (Ish) 2½–4; (SA) 4–6; (T) 4½–9	1–2 (2–4 mL)	Up to 60 mL
Ropivacaine (Naropin)	0.5%, 0.75, and 1%	5 min (2–4 h)	Not yet described	Not yet described	Up to 100 mL

<sup>a</sup>(A), anserine bursa; (IP), iliopsoas bursa; (Ish), ischial bursa; (SA), subacromial bursa; (T), trochanteric bursa.

There are more concentrated preparations available (e.g., a 2% lidocaine solution) for use in procedures where minimal injectable volume is desirable, for example, digital nerve blocks and acromioclavicular joint injections.

The smallest effective should always be used. Dosages should be adjusted for factors such as a patient's age and general health, because children, the elderly, debilitated, and acutely ill patients are at greater risk for anesthetic toxicity; individuals with hepatic dysfunction or reduced hepatic blood flow (e.g., those taking  $\beta$ -blockers or those with congestive heart failure [CHF]) are at risk as well. Anesthetic doses should also be adjusted according to the systemic absorption rate at the site of injection. Injection into the intercostal and epidural regions warrants lower doses because these areas are highly vascular and hence produce a large increase in the serum concentration. Subcutaneous tissues, in contrast, have low perfusion and require higher doses.

### Other Medications Sometimes Used in Conjunction with Local Anesthetics

#### Epinephrine

Epinephrine counteracts the anesthetic's vasodilation property and therefore slows systemic absorption rate at the site of injection. Coadministration of this agent with anesthetics can potentiate and prolong analgesic effects, as the effective dose is maintained longer. Epinephrine is also used to dilute high-dose preparations to prevent anesthetics-associated systemic side effects. Concentrations between 2 and 10  $\mu\text{g/mL}$  (i.e., ratio from 1:500,000 and 1:100,000) are generally used.

Despite its benefits, epinephrine may expose patients to additional side effects such as wound infection, tachycardia, and hypertension (HTN). It is generally believed that tissue ischemia can occur when the mixture is injected into body regions, the digits in particular, that have compromised or limited blood supply. The other concern is that epinephrine solutions contain sodium metabisulfite, which can cause an allergic reaction in certain individuals (118).

#### 7.5% Sodium Bicarbonate

Lidocaine leaves a memorable burning sensation upon intradermal and subcutaneous injection because lidocaine solutions are acidic in part due to the preservative contained in multidose bottles. The addition of epinephrine worsens the sting by further decreasing the pH. This unpleasant feeling can be minimized by buffering a lidocaine solution with 7.5% sodium bicarbonate at a 9:1 ratio (e.g., 2 mL sodium bicarbonate added to 20 mL of 1% lidocaine) (119,120). The mixture should be within 24 hours to avoid risk of contamination due to the unclear effect upon the preservative when the solution has been buffered.

### Relevant Side Effects and Drug Interactions

Amide anesthetics have a wide therapeutic index. Although toxicity can occur and it is dose related, when used alone, lidocaine and bupivacaine have maximal recommended doses of 5 and 2 mg/kg, respectively (121,122). Spinal injections carry higher likelihood of significant toxicity from possible inadvertent intrathecal administration. Toxicity manifestation can be divided into two categories: local and systemic. Local toxicity encompasses a variety of irreversible neurovascular changes (e.g., paresthesia). Systemic toxicity, albeit uncommon, can affect the CNS followed by the cardiovascular system (114). The patient may initially complain of drowsiness, tremors, and altered special senses; but, as serum level of the offending agent increases, arrhythmia, seizure, and respiratory/cardiac arrest can develop (123). Lipid infusion can reportedly treat late-phase systemic toxicity (124).

Because local anesthetics are CNS depressants, they should not be combined with another CNS depressant. Anesthetics can enhance the action of neuromuscular-blocking agents. Preparations containing epinephrine should not be given concomitantly with MAOIs or TCAs due to risk for severe HTN.

## LOCAL ANESTHETICS—TOPICAL ANESTHETICS

In addition to the injectable preparations, local anesthetics are available as a cream and as a transdermal (TD) patch that are sometimes employed for preprocedural soft tissue anesthesia. Topical lidocaine patch has also become a recommended first-line treatment for postherpetic neuralgia and is becoming increasingly used off-label for various neuropathic and musculoskeletal pain conditions (125,126).

### Eutectic Mixture of Local Anesthetics

Eutectic mixture of local anesthetics (EMLA) cream is an emulsion composed of 2.5% prilocaine and 2.5% lidocaine droplets. This topical compound has a lasting anesthetic effect for up to 4 hours (127). It can be applied to intact skin an hour prior to painful outpatient procedures. Numerous studies confirmed its efficacy over placebo cream, ethyl chloride, subcutaneous lidocaine, and iontophoresis (128). Although EMLA was deemed less effective than intradermal lidocaine, it is nonetheless preferred by patients (129).

### Lidocaine Cream and Patch

Lidocaine cream (LMX) is regarded as an equivalent of EMLA but with faster onset of action (i.e., half an hour vs. 1 hour) (130). The patch form, with a dual mechanism of nociceptive sensation blockade and a mechanical barrier from friction against injured skin, is FDA approved for treatment of postherpetic neuralgia pain. There is also new evidence that lidocaine patches are effective for other neuropathic pain, low back pain, and OA of the knee (125,131,132). Two small, uncontrolled studies reported significant pain relief in reflex sympathetic dystrophy (RSD)/complex regional pain syndrome, stump neuroma pain, intercostal neuralgia, post-thoracotomy pain, and meralgia paresthetica as well (133,134).

The branded lidocaine patch, Lidoderm, contains 700 mg of 5% lidocaine. The recommended guideline to treat postherpetic neuralgia is to apply a maximum of three simultaneous patches on intact skin for 12 hours a day. Clothing may be worn over the application area. Weaker preparations of both the cream and patch can be found OTC.

## LET

Both LET solution and gel are formulated with 4% lidocaine, 0.1% epinephrine, and 0.5% tetracaine. The gel has obvious advantages over the liquid form and is widely used half an hour before suturing uncomplicated facial and scalp lacerations (135). LET can also ameliorate pain from infiltrative anesthesia. Doses between 1 and 3 mL are effective in the aforementioned procedures. LET is not effective when used to anesthetize large wounds on the trunk or extremities at recommended doses.

## LT Peel

A 7% lidocaine and 7% tetracaine cream dries within half an hour of application and is then peeled off. There is evidence that it is superior to EMLA in adults undergoing cutaneous procedures (136).

### Relevant Side Effects and Drug Interactions

Topical agents are associated with potential side effects that are similar to their injectable counterparts except that the TD mode of delivery has a predilection to cause local skin irritation. This generally consists of mild redness and irritation at the application site. Importantly, these local reactions are usually not due to anesthetic allergy. Overall, topical anesthetics are safe. No serious adverse events have been observed in more than 120,000 patch hours in patients who used the patch for up to 8.7 years (137,138).

However, topical anesthetics should be used cautiously in patients who are taking class I antiarrhythmics (e.g., tocainide and mexiletine) as the toxic effects of both drugs are potentially synergistic.

## MUSCLE RELAXANTS

### Relevance to Physiatry

Unlike antispasticity agents, muscle relaxants are not indicated for true skeletal muscle spasticity. They are instead intended for short-term use in musculoskeletal conditions where muscle “tightness” is one of the primary pain generators. A recent meta-analysis supports this indication and showed that muscle relaxants provided modest short-term pain relief in the treatment for patients with back pain (139). Although there are no published studies comparing the relative efficacy of acetaminophen, NSAIDs and muscle relaxants appear to offer some benefits in patients with non-specific back pain.

Muscle relaxants act by decreasing muscle excitability and thus diminishing tension-induced pain. Unlike antispasticity agents, muscle relaxants offer the advantage of not compromising muscle strength. Unfortunately, sedation limits their application and sometimes obliges physicians to prescribe them for bedtime use only. Cyclobenzaprine, methocarbamol, and carisoprodol are some of the most commonly prescribed muscle relaxants.

### Mechanism of Action and Pharmacokinetics

Muscle relaxants are a unique group of medications as they have different mechanisms and pharmacokinetics (Table 65-12). The only common denominator among them is that they all act in some fashion on the CNS, rather than at the muscle fibers level, to interrupt nociceptive signals.

### Preparations, Dosing, Relevant Side Effects, and Drug Interactions

See Table 65-12.

**TABLE 65.12 Muscle Relaxants**

Drug Name	Structural Analog	Dose (mg)	Other Properties and Side Effects
[Single agents] Carisoprodol (Soma)	Meprobamate (Equanil) Miltown	350 PO tid–qid	Sedation often occurs from muscle relaxants ? mechanism but centrally acting; sedation; first dose idiosyncratic reactions; contraindicated in acute intermittent porphyria; addictive
Cyclobenzaprine (Flexeril)	Tricyclic antidepressants	5–10 PO tid initial; max: 60 PO	? mechanism but centrally acting; widely used; plasma levels vary widely; sedation and other anticholinergic side effects; avoid use in elderly
Diazepam (Valium, Diastat)	BNZs	2–10 PO/PR bid–qid 5–10 IV/IM q3–4h	Enhances GABA effect by binding to BNZ receptors; also used as an antispasticity agent
Metaxalone (Skelaxin)	None	800 PO tid–qid	? mechanism but centrally acting; drowsiness or CNS paradoxical excitation; hematologic toxicity, esp. hemolytic anemia or leukopenia; avoid if hepatic dysfunction
Methocarbamol (Robaxin)	Mephenesin (first muscle relaxant)	1,500 qid load × 48–72 h, then 1,000 PO/IM/IV qid	? mechanism but centrally acting; IM form inconvenient since should inject into each buttock rather than entire dose into one; lowers seizure threshold
Orphenadrine (Norflex)	Antihistamines	100 PO bid 60 IV/IM bid	? mechanism but centrally acting; sedation; reports of anaphylaxis in some asthmatics with IM/IV dosing
[Muscle relaxant/analgesic] Norgesic Norgesic forte		2 tabs PO tid–qid 1 tab PO tid–qid	Contents (mg): orphenadrine 25/ASA 385/caffeine 30 Contents (mg): orphenadrine 50/ASA 770/caffeine 60 addition of ASA and caffeine is based upon a presumed synergistic effect with the muscle relaxant and decreased sedation
Soma compound		1–2 tabs PO qid	Contents (mg): carisoprodol 200/ASA 325; addictive
Soma compound with codeine		1–2 tabs PO qid	Contents (mg): carisoprodol 200/ASA 325/codeine 16; potentially quite sedative; highly addictive
Robaxinal		2 tabs PO qid	Contents (mg): methocarbamol 400/ASA 325

## N-METHYL-D-ASPARTATE-RECEPTOR ANTAGONISTS

### Relevance to Physiatry

Tissue and nerve injury enhance the release of glutamate. This excitatory amino acid then binds to *N*-methyl-D-aspartate (NMDA) receptors in the spinal cord and, in turn, modulates pain sensation. NMDA receptor antagonists (also known as *NMDA glutamatergic antagonists*) act to inhibit this pathway. There is some preliminary evidence of success in using the oral form of these agents to treat neuropathic and cancer pain (140). Other potential applications include oral/epidural preemptive analgesia prior to surgery and coadministration with opioids to improve postoperative pain relief (141–144). In addition to their independent analgesic effect, NMDA receptor antagonists are also synergists with opioids and can prevent tolerance to opioids (145).

Ketamine, dextromethorphan, memantine, and amantadine are examples from this category of medication. Two opioids (i.e., methadone and dextropropoxyphene) also possess NMDA antagonistic properties. These agents are discussed below. Other NMDA-receptor antagonists exist, but their use is significantly limited by side effects.

Several NMDA-receptor antagonist clinical trials have been discontinued due to psychomimetic adverse effects as

well as ataxia and coordination impairment (146). This has led to the development of moderate affinity channel blockers (e.g., glycine B) and NR2B selective antagonists, which selectively block peripheral NMDA receptors (147). This new generation of drugs currently displays a better side-effect profile in animal models.

### Ketamine (Ketalar)

Ketamine hydrochloride is primarily used in veterinary practices as a tranquilizer. It is approved for use in children and individuals with poor health as a general anesthetic (IV or intramuscular [IM]) and as a preoperative sedative (PO or parenteral). It causes a state of consciousness known as *dissociative anesthesia*. It does not have an official pain indication. There is no predetermined dosing guideline for its analgesic use, but a dose ranging from 6.5 to 13 mg/kg IM is administered for 12 to 25 minutes of surgical anesthesia. One study used 0.4 mg/kg IM doses to treat trigeminal neuralgia (148). There is also a case report on its successful use in complex regional pain syndrome (aka *RDS*) (149). Ketamine gel has been reported in a case series involving several different neuropathic pain conditions (150). Ketamine is classified as a schedule III controlled substance because its psychomimetic effects are comparable to snorting PCP.

### Dextromethorphan

Dextromethorphan attenuates acute pain at doses of 30 to 90 mg, divided every 4 to 6 hours (5–10 mg/mL), and reduces analgesic requirements in postoperative patients without major side effects, but it has a suboptimal analgesic effect in treatment of chronic pain (151). There is some preclinical evidence of neuroprotective properties in the setting of perioperative brain injury, amyotrophic lateral sclerosis, and methotrexate neurotoxicity (152).

### Amantadine

Amantadine is an antiviral agent with NMDA receptor antagonist properties. It is also used in Parkinson's disease and traumatic brain injury (TBI). Amantadine was unsuccessful as an agent used to prevent postmastectomy pain neuropathic syndrome (153).

### Memantine

Memantine is a moderate affinity NMDA-receptor antagonist. It is indicated for moderate Alzheimer's disease. There is some evidence from case reports and small, controlled trials on its application in neuropathic pain (154,155).

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

### Relevance to Psychiatry

Oral NSAIDs are frequently used in the outpatient musculoskeletal medicine setting. At high doses, NSAIDs display both anti-inflammatory and analgesic properties, generally without causing sedation. All NSAIDs share the same mechanism of action and overall side-effect profile, but they also have individual characteristics that distinguish them from each other. No one NSAID has been demonstrated as being superior in terms of efficacy to others. Ideally, psychiatrists should be familiar with at least one agent from each NSAID class. This will allow the physician to comfortably switch a patient off an agent from one NSAID class to an agent from a different class. This strategy can be emplaced if they do not respond and/or have side effects with use of an NSAID from one class.

### Mechanism of Action and Pharmacokinetics

NSAIDs exert their primary effects by inhibiting the synthesis of prostaglandins and other related inflammatory compounds (e.g., thromboxanes and leukotrienes). The four primary properties of NSAIDs are analgesia for mild to moderate pain, anti-inflammatory effects, antipyresis, and reversible platelet inhibition. Anti-inflammatory effects also contribute to analgesia by preventing inflammatory-mediated sensitization of nociceptors.

Oral NSAIDs are absorbed in the upper GI tract. A large percent of the drug becomes bound to plasma protein while the unbound portion exerts its pharmacological effects. NSAIDs undergo hepatic metabolism and renal excretion. NSAIDs are

available as short-acting and long-acting preparations with a half-life ranging from 30 to 50 hours at steady state. The consequence of accumulating long-acting agents (e.g., oxaprozin [Daypro] and piroxicam [Feldene]) in the human body is unclear, but to date, there are no reports of any additional significant adverse events beyond those typically seen with NSAIDs (156).

### Preparations and Dosing

Table 65-13 shows a classification scheme of NSAIDs based on their chemical structure. Additional information on the individual classes is as follows:

- *Salicylates*: These include aspirin and three nonacetylated salicylates. Compared to other NSAIDs, nonacetylated salicylates are less potent but cause less GI and platelet inhibition. It is unclear if any one particular nonacetylated salicylate in this category is more advantageous than the other two.
- *Propionic acids*: This is the most popular NSAID class due to the OTC availability of ibuprofen and naproxen, and the direct marketing of the agent to the general public.
- *Acetic acids*: This class is the most potent and most potentially toxic of all NSAIDs. It includes two drugs that can be administered via IM and parenteral routes (i.e., ketorolac and indomethacin) and two prodrugs (i.e., sulindac and nabumetone) are converted into their active counterparts.
- *Fenemates*: Meclofenamate and mefenamic acid offers no advantage over other NSAIDs but can cause significant GI toxicity and dysmenorrhea pain, respectively.
- *Oxicams*: Only piroxicam and meloxicam are currently available in the United States. Piroxicam has convenient once-daily dosing but is associated with severe dermatologic reactions such as exfoliative dermatitis and pemphigus vulgaris. The risk of adverse effects is lower for meloxicam. It was FDA approved for treatment of pain due to OA in 2004.

### Relevant Side Effects and Drug Interactions

Individuals regularly using NSAIDs have up to five times the risk of developing GI complications (157). NSAIDs act directly to increase gastric acid secretion and indirectly to inhibit prostaglandin, which protects the GI tract lining. The direct effect varies among NSAIDs and only occurs with oral administration. The direct effect, on the contrary, remains constant regardless of the rate of administration. The elderly and patients with a history of peptic ulcer disease are particularly vulnerable to epigastric discomfort and ulceration. Recent studies indicate that piroxicam and ketorolac confer the highest GI risks at low dose and ibuprofen confers the least (158). The theory behind relative GI risks is that certain NSAIDs undergo extensive biliary excretion of their active metabolites and this, in turn, prolongs mucosal contact.

Simple strategies to decrease risk of GI complications include taking NSAIDs with meals and selecting enteric-coated

**TABLE 65.13 Nonsteroidal Antiinflammatory Drugs (NSAIDs)**

Drug Name	Dose (Oral in mg)	Other Properties and Side Effects
[Salicylates: acetylated] Aspirin (Ecotrin, Anacin, Bayer)	325–650 q4–6h 81–325 daily cardioprotective	Used: especially for antipyretic and cardioprotective effects Other formulations available: 800 mg controlled release (prescription only) 975 mg enteric-coated (prescription only) suppositories: 120, 200, 300, 600 120, 200, 300, 600 600 mg combined with narcotics and muscle relaxants Side effects: allergy esp. if triad of nasal polyps, hay fever, asthma; GI toxicity but enteric-coated and buffered forms exist; tinnitus; Reye syndrome in children
[Salicylates: nonacetylated] Diflunisal (Dolobid)	500–1,000 load then 250–500 q8–12h	Relatively weak anti-inflammatory effect; lacks antipyretic activity
Salsalate (Disalcid, Salflex)	3,000 divided q8–12h	Relatively weak anti-inflammatory effect; no platelet inhibition
Salicylate combination (Trilisate)	1,500 bid	Relatively weak anti-inflammatory effect;? no ASA-allergic reactions; liquid preparation available (500 mg/5 mt)
[Propionic acids] Flurbiprofen (Ansaid)	200–300 divided bid–qid	Available in ophthalmic solution (Ocufen); TO form available
Ibuprofen (Motrin)	200–800 tid–qid	Inexpensive and widely used; frequent dosing; (OTC): Advil, Motrin IB; Naprin, Rufen;TD form available
Ketoprofen (Ordis, Actron)	25–75 tid–qid	Accumulates if poor renal function
Naproxen (Naprosyn, Aleve)	250–500 bid	High-incidence GI side effects; advantage of enteric-coated form?, although expensive; (OTC): Aleve;
(EC-Naprosyn)	375–500 bid	
Naproxen-Na (Naprelan)	750–1,000 qd	Naprelan has Intestinal Protective Drug Absorption System (IPDAS);
(Anaprox)	275–550 bid	IR- and SR components
Oxaprozin (Daypro)	600 mg bid; 1,200 qd	qd or bid dosing
[Acetic acids] Diclofenac (Cataflam, Voltaren)	50 bid- tid or 75 bid	LFT monitoring if prolonged use; side effects in up to 20%;
(Voltaren-XR)	100–200 qd	Arthrotec = diclofenac (50 or 75 mg) + misoprostol (200 µg)
Etodolac (Lodine)	200–400 bid-tid	Gastric-sparing properties?
(Lodine XL)	400–1,200 qd	
Indomethacin (Indocin)	25–50 tid	Most potent and toxic NSAID; PR preparation (Indotec); drug of choice in ankylosing spondylitis; indicated in other highly inflammatory conditions (e.g., acute gouty arthritis); Prevents heterotopic ossification s/p total hip replacement (THR) and used for myositis ossificans; dose- related CNS/ hematologic side effects in up to 25–50%; GI toxicity
(Indocin-SR)	75 qd	
Ketorolac (Toradol)	15–30 IV/IM q6h or 10 q4–6h prn Lower doses if age >65 or renal dysfunction	FDA-approved only for 5 consecutive days; GI bleeding at higher doses; rapid analgesia with IM form—decrease dose for age ≥ 65, renal dysfunction, weight <110; IV preparation also available
Nabumetone (Relafen)	1,000 initially then 1,500–2,000 qd or divided bid	qd or bid dosing; nonacidic prodrug that undergoes hepatic biotransformation into active metabolite; preliminary studies suggest that unlike other NSAIDs, no evidence of enterohepatic recirculation of active metabolite—this may be an advantage
Sulindac (Clinoril)	150–200 bid	Prodrug; possibly renal-sparing because urinary excretion, primarily as biologically inactive forms, may be more GI toxic
Tolmetin (Tolectin)	200–600 tid	Frequent dosing; frequent GI toxicity
[Fenemates] Meclofenamate	50–100 tid–qid or	Frequent dosing; diarrhea common
Mefenamic acid (Ponstel)	500 initially, then 250 mg q6h prn for ≤1 wk	Frequent dosing; used for dysmenorrheic pain
[Oxicams] Piroxicam (Feldene)	20 qd	qd dosing; accumulation in older adults possibly due to enterohepatic recirculation; dermatologic side effects and cases of serum sickness; PR form (Fexicam)
Meloxicam (Mobic)	7.5 qd	

**TABLE 65.14 Agents Used in NSAID-Induced Upper GI Toxicity Prophylaxis/Treatment**

Medication	Dose Range	Gastric Ulcer (NSAID-Induced)	Duodenal Ulcer (NSAID-Induced)
Antacids	Standard	Not preventative	Not preventative
H <sub>2</sub> blockers	Standard	Not preventative	Preventative
	High dose	Preventative?	Preventative
Misoprostol (Cytotec)	Standard (200 µm qid)	Preventative (FDA approved)	Not preventative
	Low (200 µg bid-tid)	Preventative?	Not preventative
PPIs	Standard	Not preventative	Preventative?
Sucralfate (Carafate)	Standard (1 g qid)	Not preventative	Healing (if stop NSAIDs)

preparations. Prophylactic medications can be given if the patient has concomitant use of corticosteroids, warfarin, or a history of GI bleeding or peptic ulcer disease (Table 65-14). The classes of available medications include antacids, H<sub>2</sub> blockers, misoprostol, proton pump inhibitors (PPIs), and sucralfate (Table 65-14). Only misoprostol and PPIs are FDA approved for gastric ulcer prevention and H<sub>2</sub> blocker has not been shown to be effective in chronic NSAID users (159). Misoprostol is recommended over PPIs in patients without active *Helicobacter pylori* infection (160). Ideally, the selected prophylactic medication should be taken for the duration of NSAID therapy in order to provide maximum protection.

Less common GI side effects involve the esophagus, the nonduodenal portion of small bowel, colon, and liver. Esophageal side effects include esophagitis and benign esophageal strictures. Irritable bowel disease can be unmasked while the small bowel and colon can develop ulcers, erosions, and web-like strictures. NSAID enteropathy is not believed to occur via an acid mechanism and is therefore not prevented by antacids, H<sub>2</sub> blockers, or PPIs.

A large study in 2005 found that NSAIDs are the second main cause of drug-induced liver injury. Despite this, hepatotoxicity is rare except in individuals with a history of liver disease (161). Clinically, significant hepatic enzymes elevation does occur with certain NSAIDs, particularly diclofenac. When employing these NSAIDs, LFTs are recommended throughout the course of treatment. There is however currently no established specifically recommended schedule for liver function testing.

In large part due to studies of coxibs (see below), all NSAIDs now carry a black box warning that warns against potential cardiovascular and GI side effects. This is discussed in more detail in the coxib section below.

Individuals with preexisting kidney disease or comorbid medical conditions that impair renal blood flow (e.g., CHF and hypovolemia) are prone to acquire NSAID-induced renal toxicity. Acute renal failure, nephrotic syndrome, and interstitial nephritis are examples. It has been suggested but not proven that sulindac is somewhat renal sparing compared to other NSAIDs (162).

In light of all adverse effects discussed above, a significant amount of research has been dedicated to find an alternative

to traditional NSAIDs. The effort yielded only one product, the COX-II inhibitor celecoxib, that is still available on the market and it will be further explored in the following section. More options are currently under investigation. They include dual COX and 5-lipoxygenase (5-LOX) inhibitors, synthetic lipoxins, nitric oxide-releasing NSAIDs, and hydrogen sulfide-releasing NSAIDs (163). The mechanism of action for these drugs involves either combining current NSAIDs with a moiety (i.e., nitric oxide and hydrogen sulfide) that releases gastroprotective mediators or targeting new processes of the inflammatory process.

True NSAID allergic reactions occur in 1% of the population and range from simple skin rashes and rhinitis to anaphylaxis. NSAIDs should not be used in patients allergic to aspirin.

## CYCLOOXYGENASE-II INHIBITORS

### Relevance to Psychiatry

COX-II inhibitors (also known as *coxibs*) represent an alternative to NSAIDs. Coxibs in general were generally thought to confer the advantage of less GI toxicity compared to traditional NSAIDs. This appeal led to them becoming the most frequently prescribed new medication within the first year of being introduced in 1999. However, much has changed since the turn of the century. For example, the two other previously available coxibs, rofecoxib (Vioxx) and valdecoxib (Bextra), were withdrawn from the market in 2004 due to an increased risk of cardiovascular toxicity as is discussed in more detail below. Celecoxib, the only currently available coxib at the time of this writing, is FDA approved for the treatment of pain associated with rheumatoid and OA, and for acute pain. Celecoxib is especially used in those individuals who require oral anti-inflammatories but are on concomitant anticoagulation therapy, are at high risk for GI side effects, or are to undergo certain injection procedures such as fluoroscopic-guided spinal injection procedures or injection procedures into deep joint structures, where the risk of inadvertent bleeding makes the use of traditional NSAIDs potentially dangerous (164,165). There also continues to be interest in coxibs because COX-II expression is implicated in colon cancer and Alzheimer's disease (165).

**TABLE 65.15 Celecoxib: Recommended Doses for Approved Indications**

Indication	Celecoxib (Celebrex): Capsules (mg) 50; 100; 200
Acute pain or primary dysmenorrhea	400 mg first dose, then another 200 mg on day 1 prn, then 200 mg bid prn thereafter
Ankylosing spondylitis	200 mg qd or 100 mg bid, then 400 mg qd if no effect after 6 wk
Osteoarthritis	200 mg qd or 100 mg bid
Familial adenomatous polyposis	400 mg bid
Rheumatoid arthritis—adults	100–200 mg bid
Rheumatoid arthritis—juvenile (≥2 years old)	≥10 kg to ≤25 kg: 50 mg bid; >25 kg: 100 mg bid

### Mechanism of Action and Pharmacokinetics

Coxibs reduce prostaglandin synthesis by selectively inhibiting one isoform of cyclooxygenase enzyme over another—namely, COX-II over COX-I. This mechanism contrasts with that of NSAIDs, which inhibit COX-II and COX-I equally. COX-I is constitutively expressed in all human tissues including the GI tract. Only a low level of COX-II is constitutively expressed in brain, kidney, bone, and female reproductive tissues; however, the expression of COX-II can be induced at sites of inflammation. By sparing COX-I, coxibs achieve comparable anti-inflammatory and analgesic effects, with less adverse GI toxicity. The lack of effect on thromboxane synthesis explains the absence of antiplatelet effect.

Food has no significant effect on either peak plasma concentration or absorption at therapeutic doses. Higher doses (≥400 mg bid) should, however, be taken with food to improve absorption.

### Preparations and Dosing

Celecoxib is available as 100-mg, 200-mg, and 400-mg capsules. It is currently only approved for the indications as shown in Table 65-15. The lowest effective dose should be used, especially in patients with HTN or CHF because coxibs may cause renal prostaglandin-mediated fluid retention. In patients with moderate hepatic impairment, doses should be decreased by approximately 50%.

### Relevant Side Effects and Drug Interactions

Clinical trials found that coxibs caused less gastropathy than traditional NSAIDs; the most notable trials included the VIGOR (Vioxx GI Outcomes Research), TARGET (Therapeutic Arthritis Research and GI Event Trial), and CLASS studies (Celebrex Long-term Arthritis Safety Study) (166–168). There is however growing evidence that coxibs impair healing of damaged gastric mucosa and may negatively affect both the small and the large intestines (169–171). These findings have led to further questioning as to whether there really is an advantage of less GI toxicity from coxibs over traditional NSAIDs (163).

Coxibs can cause a dose-dependent risk of adverse cardiovascular events, including myocardial infarction and stroke (172,173). Rofecoxib was withdrawn upon completion of the 3-year APPROVe study, which showed that daily intake of 25 mg of this coxib doubled the risk of thrombotic events (174). It was also shown that doubling the dose of celecoxib

increased adverse cardiovascular events by (risk ratio, 3.4; 95% confidence interval, 1.5 to 7.9) above that of the 200 mg qd Celebrex dose (2.6; 95% CI, 1.1 to 6.1) (175,177). The pathophysiology behind this effect is that coxibs inhibit vascular endothelium production of prostaglandin I<sub>2</sub>, a lipid that counteracts thromboxane A<sub>2</sub> to prevent platelet aggregation leading to atherosclerosis, and cause a similar blood pressure (BP) elevation as NSAIDs (176). It is not known if cardioprotective aspirin or low-salt diet can mitigate coxibs' cardiovascular risks (177).

This issue of increased cardiovascular risk led to a black box warning that is now part of the package inserts of celecoxib and all NSAIDs as follows:

### Cardiovascular Risk

- NSAIDs and celecoxib may cause an increased risk of serious cardiovascular thrombotic events, myocardial infarction, and stroke, which can be fatal. This risk may increase with duration of use. Patients with cardiovascular disease or risk factors for cardiovascular disease may be at greater risk.
- NSAIDs and celecoxib are contraindicated for the treatment of perioperative pain in the setting of coronary artery bypass graft (CABG) surgery.
- GI risk.
- NSAIDs and celecoxib cause an increased risk of serious GI adverse events including bleeding, ulceration, and perforation of the stomach or intestines, which can be fatal. These events can occur at any time during use and without warning symptoms.
- Elderly patients are at greater risk for serious GI events.

Traditional NSAIDs and coxibs have equal potential to cause renal toxicity (e.g., fluid retention leading to edema, renal HTN, interstitial nephritis, and papillary necrosis) (178,179). Elderly patients with renal insufficiency or hepatic failure and individuals at risk for renal failure should avoid coxibs (180).

Mean INR can increase up to 10% for a subset of patients receiving both warfarin and coxibs, and there have been infrequent reports of increased INR associated with bleeding events (159). This notion however was subsequently challenged by the results of a randomized, controlled, crossover trial to assess the effect on INR of celecoxib in 15 patients who were receiving warfarin therapy (181). Nonetheless, patients on anticoagulation therapy should have their INRs monitored when a coxib is initiated or its dose changed.

**TABLE 65.16 A Sample of COX-II Inhibitor-Medication Interactions**

COX-II Inhibitor	Medications that Alter COX-II Inhibitor Concentration	Medications Whose Concentration is Altered by COX-II Inhibitor
Celecoxib	Fluconazole (increases) Rifampin (decreases) Fluconazole (increases) Ketoconazole (increases)	Lithium (increases) Methotrexate (increases) Dextromethorphan (increases) Lithium (decreases)

There are case reports of celecoxib having induced serious skin reactions such as toxic epidermal necrolysis, erythema multiforme, and Stevens-Johnson syndrome (182,183). Celecoxib is contraindicated in sulfonamide allergy (approximately 3% of the general population) and in patients with a history of aspirin or NSAID allergy.

Prostaglandins are involved in bone metabolism and animal models show that coxibs reduce bone, tendon, and ligament healing. Although clinical trials on humans have yet to be undertaken, many orthopedists and physiatrists avoid coxibs in patients with fractures (184,185).

The main potential drug interactions involving coxibs include those with angiotensin-converting enzyme (ACE) inhibitors and diuretics. Specifically, celecoxib can interfere with the antihypertensive effects of those agents. Medications that alter celecoxib's serum concentration and whose concentrations are altered by celecoxib are summarized in Table 65-16.

## OTHER ADJUVANT ANALGESICS

### Tizanidine (Zanaflex)

#### Relevance to Physiatry

Tizanidine was developed as an antispasticity agent and is approved for use in spasticity due to multiple sclerosis or SCI. It has also been studied for acute low back pain accompanied by muscle "spasm" and neuropathic pain conditions, including trigeminal neuralgia and phantom pain syndrome (186–188). An open-label study in humans concluded that tizanidine may be an effective treatment for pain associated with idiopathic peripheral neuropathy, and another animal study showed that it relieved thermal hyperalgesia in rats with induced neuropathic pain (189,190). However, there are no large, randomized clinical trials to date on its use in neuropathic pain. Other indications that are not as applicable to physiatry include its use along with long-acting NSAIDs for detoxification of rebound headache, chronic tension headache, and narcotic withdrawal (191–193).

#### Mechanism of Action and Pharmacokinetics

Tizanidine is a centrally acting  $\alpha_2$ -adrenergic agonist which presumably reduces spasticity by increasing presynaptic motor neuron inhibition. Following oral administration, 95% of

the dose undergoes first-pass hepatic metabolism to inactive metabolites and peak plasma level is reached in 1.5 hours. Concomitant food intake decreases peak plasma concentration and increases the time it takes to reach peak level (194).

#### Preparations and Dosing

Tizanidine is available in 2-, 4-, and 6-mg scored tablets. Dosing for spasticity is accomplished by gradually increasing a starting dose of 4 mg by 2 to 4 mg until a daily maximum of 36 mg divided tid is reached; the desired therapeutic effect is achieved or dose-limiting side effects occur. Although the maximum total daily dose is generally denoted as 36 mg, clinical experience beyond 24 mg is limited. Dosing guidelines for myofascial and neuropathic pain have not yet been established as these uses are considered off-label.

#### Side Effects and Medication Interactions

Hypotension, dry mouth, CNS depression, and muscle weakness are commonly associated with  $\alpha_2$ -adrenergic antagonism. Muscle weakness associated with tizanidine is comparatively less than with other antispasticity agents (195).

The most clinically significant side effect, though rare, is hepatotoxicity. In controlled clinical studies, 5% of participants had serum transaminase elevated three times that of normal (or twice if baseline levels were elevated); most cases resolved upon medication withdrawal but some individuals developed nausea, vomiting, anorexia, and jaundice. Liver function testing is recommended during the first 6 months (i.e., baseline, 1, 3, and 6 months) of initiating tizanidine therapy and then periodically monitored. Tizanidine should be used with caution in patients with impaired hepatic function.

Oral contraceptives lower tizanidine clearance (196). There are also limited case reports of tizanidine interaction with fluvoxamine, lisinopril, and ciprofloxacin (197–199).

## OPIOID ANALGESICS

### Relevance to Physiatry

Narcotic analgesics are often referred to as *opioid* or *opiate analgesics*, as some are opium derived. They are indicated for moderate to severe acute and ongoing malignant pain, especially that which is of a nociceptive quality (i.e., generally

dull or aching). In contrast, opiate analgesics are considered second-line treatments for various neuropathic pain syndromes such as phantom leg pain, diabetic neuropathy, and postherpetic neuralgia (200–202). These indications are partly adapted from the World Health Organization (WHO) three-step ladder that guides analgesic treatment (203). The first step consists of nonopioid analgesics and adjuvants. Weak opioids (e.g., codeine) comprise the second step of pain management when the first-step options have failed. Step three consists of strong opioids (e.g., morphine) plus or minus the first-step options.

The lack of end-organ toxicity (especially GI, hepatic, and renal) with pure narcotic analgesics, other than meperidine, makes them an appealing choice for chronic therapy. However, the potential for serious adverse events (e.g., respiratory depression) represents a drawback (204).

More common side effects associated with opioid analgesics include nausea, vomiting, constipation, sedation, euphoria, tolerance, and physical/psychological dependence. There may be minor variations to this side-effect profile for individual agents (i.e., some have more pronounced side effects than others at equivalent doses) (205,206). Since all pure opioid agonists have equianalgesic doses with each other, selection of a specific agent is based upon the desired route of administration, duration of action, and desired side effect.

Other physiatrie applications for opioids include diarrhea treatment and cough suppression—the latter is particularly pertinent for patients with nonproductive cough that is interfering with sleep and, thus, their rehabilitation. The recent discovery of opioid receptors beyond the CNS has led to much interest in “peripheral opioid analgesia”; there is now evidence that IM, intra-articular, and IV injection of low-dosed opioid provide localized, peripheral analgesia, and anti-inflammation (207–211).

### Mechanism of Action and Pharmacokinetics

This class of medication mimics the action of opioids naturally produced by the body. Endorphins, enkephalins, and dynorphins are examples of these endogenous opioids. All opioids exert their effects by binding, with varying degrees of affinity, to three primary receptor types: mu ( $\mu$ ), kappa ( $\kappa$ ), and delta ( $\delta$ ). Each receptor type has a unique CNS distribution and results in different physiologic responses, via variable biochemical pathways. Receptors have also been identified in immune cells, peripheral sensory nerves, and joints; these sites account for the peripheral analgesic and anti-inflammatory effects of opioids (212,213). The unifying property among all opioid receptors is that they are coupled to a G-protein, which inhibits adenylyl cyclase. An activated receptor acts via its specific biochemical pathway to inhibit neuronal excitability and thus, blocks pain impulse transmission.

Opioid analgesics can be categorized based on their affinity for a receptor and their intrinsic activity (i.e., amount of receptor stimulation they can produce). Morphine and methadone are designated as full agonists because they have high affinity for receptors and produce strong analgesia. Partial agonists, such as codeine, have lower affinity and are thus less

potent than full agonists. Pentazocine is an example of a mixed agonist/antagonist that can activate unoccupied opioid receptors while blocking occupied ones. Antagonists (e.g., naloxone) are effective in reversing the effects of a full opioid agonist.

Slightly basic opioids are generally well absorbed in the small intestine. Short-acting agents demonstrate maximal effects between 30 and 60 minutes of administration and have durations of approximately 4 hours. Long-acting or SR agents achieve peak effects within 2 to 24 hours and last for 12 to 72 hours—the first value correlates with oral administration and the second value correlates with TD application. Many opioids undergo first-pass metabolism in the liver. Hepatic conjugation is the primary route of metabolism for most opioids but metabolism can also occur in the kidneys, lungs, and CNS. Active and inactive metabolites are excreted in urine and/or bile.

### Preparations and Dosing

Opioid analgesics can be administered orally, intramuscularly, intravenously, subcutaneously, intraspinally, intranasally (as naloxone), rectally (as hydromorphone), transdermally (as fentanyl patch), and transmucosally (as fentanyl buccal tablet). The preferred route of administration and duration of action (i.e., long acting versus short acting) will vary for a given patient. Short-acting agents can be used to manage acute pain syndromes and episodes of breakthrough pain. Long-acting agents are generally more convenient for patients with chronic conditions and their sustained effects often help prevent pain-related nocturnal awakening.

Opioid preparations most relevant to psychiatry, along with their usual dosage ranges and relative potencies, are shown in Table 65-17; although partial agonists and mixed agonist/antagonist are listed on the table, they have limited application. Required oral doses are greater than parenteral ones because of first-pass effect following oral administration. The management of neuropathic pain usually requires higher doses than for nociceptive pain.

Patients requiring chronic opioid therapy are often initiated on a short-acting agent that is titrated over several weeks to achieve adequate analgesia, and then converted to an equivalent dose of the long-acting agent (214). Doses can be titrated as high as necessary to relieve pain as long as they are tolerated well. Studies have shown that daily doses up to 120 mg of morphine equivalent can provide pain relief and improve sleep, without impairing cognitive function (202,214,215). Opioid rotation, which involves replacing one opioid with one that has incomplete crosstolerance for the original, is a technique that is used in an attempt to avoid tolerance buildup and to overcome dose-limiting side effects (216,217). An individual is considered to be tolerant to opioid therapy when he/she is consuming more than 60 mg oral morphine daily, more than 25 mcg TD fentanyl hourly, more than 30 mg oxycodone daily, more than 8 mg hydromorphone daily, or equivalent dose of another opioid for more than 1 week (218).

WHO recommends that all opioid therapies follow a fixed-interval dosing schedule, rather than being dispensed

**TABLE 65.17    Narcotic Analgesics**

as needed (prn) (203). This strategy helps maintain a stable serum medication level and, in turn, minimizes side effects experienced at peak levels and breakthrough pain at trough levels. Another recommendation is for health care providers to recognize individual variability in opioid metabolism and pain tolerance. Therapy must therefore be individualized to maximize analgesia while minimizing side effects. Other guidelines within this document are designed to help optimize opioid analgesics use and minimize the side effects.

## INDIVIDUAL AGENTS

### Partial Agonists

#### Codeine

Codeine is a natural opioid present in opium that can be used as an analgesic, antitussive, or antidiarrheal agent. It possesses less than one-seventh the analgesic potency of morphine and is often either combined with acetaminophen or used concomitantly with NSAIDs to manage mild to moderate pain (219). It has a relative lack of respiratory depression and a low abuse potential (due to its relative lack of euphoria)—thus posing a lower abuse potential. Codeine has a high oral bioavailability because its phenyl ring shields the molecule from first-pass metabolism. Following administration, codeine is demethylated to morphine, an active metabolite and an inactive metabolite, norcodeine; these metabolites are then hepatically conjugated and most are renally excreted. Individuals unable to convert codeine to morphine would experience negligible analgesic effects.

Potential adverse effects associated with codeine are typical of narcotic analgesics in general. Codeine is regulated under

the Controlled Substances Act. Codeine is considered to be unsafe when consumed at high doses or for prolonged time during pregnancy. Some codeine-containing preparations may contain sodium metabisulfite, a potentially allergenic preservative. SR codeine, codeine Contin, is available outside the United States for chronic pain management (220).

#### Propoxyphene (Darvon, Darvon Pulvules, Dolene)

This narcotic analgesic is a synthetic structural analogue of methadone. It has two isomers: one has antitussive effects while the other has one half to two thirds of the analgesic potency of codeine (219). The latter isomer offers an alternative to individuals who cannot metabolize codeine and is often combined with acetaminophen or aspirin to manage mild to moderate pain. Propoxyphene, unlike codeine, undergoes extensive first-pass metabolism and is converted into norpropoxyphene, which has local anesthetic effects and may accumulate with repeated dosing. Toxic levels of the active metabolite from chronic administration or acute overdose can lead to arrhythmias, cardiogenic shock, respiratory depression, hallucination, seizures, and death. Contrary to the general rule that opioid agonists do not have an analgesic ceiling, propoxyphene doses should not exceed 390 mg/day. The concomitant intake of propoxyphene with another CNS depressant should be avoided, and caution should be exercised when prescribing it to patients with preexisting hepatic dysfunction because propoxyphene therapy has been associated with hepatotoxicity, including rare instances of reversible cholestatic jaundice. Several nursing home specialists advise against the use of propoxyphene in geriatric population (221). In practice, however, some physicians may select propoxyphene when it the only viable opioid option.

## Full Agonists

### Fentanyl-TD (Duragesic), Fentanyl-Transmucosal (Actiq, Fentora)

Fentanyl is a potent (i.e., >80 times of morphine), short-acting opioid with therapeutic uses including analgesia, preprocedural anxiolysis, sedation, and supplemental anesthesia. It is available as an injectable preparation, a nebulized preparation, a TD patch, and a transmucosal lozenge/tablet. Management of terminally ill patients with dyspnea and is an off-label use of nebulized fentanyl (222).

A TD delivery system for fentanyl is possible because it has a low molecular weight and is highly lipophilic, which enables the drug to be absorbed through the skin and subsequently distributed throughout the body. The fentanyl patch, with an average duration of 72 hours, is used to manage chronic pain that requires regular administration of narcotic analgesics. The advantages of TD fentanyl include lower incidences of constipation, nausea, and drowsiness (223). Cutaneous reactions are limited to localized dermatitis, but systemic adverse effects may occur. The patch cannot be used in acute pain syndromes because initial absorption is delayed for 17 to 48 hours, and it should not be used due to the risk of significant hypoventilation in narcotic-naïve patients. There is, however, a recent trend of employing a patient-controlled iontophoresis TD system to manage acute postoperative pain within inpatient settings (224–226).

When initiating a fentanyl patch therapy for narcotic-naïve patients, one should start with the lowest available dose (currently 12.5 mcg/hour). There is a wide variability of absorption among patients and titration can be accomplished by combining various available patch strengths (i.e., 25, 50, 75, and 100 mcg/h) (227). As for patients who are accustomed to opioid therapy, the initial dose is estimated from previous equianalgesic morphine doses. Fever, diaphoresis, cachexia, morbid obesity, and ascities can all affect the rate of TD absorption and dosage should hence be adjusted accordingly (228). Physicians involved in pain management should also become familiar with dosage titration, discontinuation strategies, and drug interactions for the fentanyl patch.

With an average onset of action in 5 minutes, transmucosal delivery provides a rapid route of absorption into the bloodstream. The lozenge and the buccal tablet are only FDA approved for treatment of breakthrough cancer pain in patients who are tolerant to their current opioid therapies, but various off-label uses have been reported (229–232). Dosing should be individualized to achieve adequate analgesia with tolerable side effects. If the pain is not relieved following transmucosal administration, a second dose of lozenge and buccal tablet can be administered 15 and 30 minutes after completion of the first, respectively (233). Patients should not exceed four units per day. Single doses between 100 and 800 mcg are generally well tolerated, causing mild-to-moderate opioid-associated side effects (234).

### Hydromorphone (Dilaudid)

This semisynthetic opioid is derived from morphine. These two compounds have similar pharmacokinetic profiles, except

that hydromorphone has a shorter duration of action but five times the analgesic efficacy. An open-labeled study found that hydromorphone causes less nausea, emesis, and constipation (235,236). Hydromorphone may be a valuable alternative for patients with “pseudoallergy” (e.g., flushing and itching due to histamine release) to morphine in managing moderate to severe chronic pain because it appears to induce minimal histamine release (237). It is also preferred for patients with renal failure because its metabolite is nontoxic (238). Finally, hydromorphone’s superior water solubility allows high doses to be dissolved into solution and delivered to opioid-tolerant patients.

Several hydromorphone-containing products are FDA approved as antitussives and a nebulized form is available for off-label use in terminally ill patients with dyspnea (222,239). Although hydromorph Contin remains available in Canada, a similar extended-release formulation was withdrawn from the U.S. market in 2005 due to a high risk of overdose when consumed with alcohol.

### Meperidine (Demerol)

Once a popular fast-acting agent used for management of moderate-to-severe postoperative pain, meperidine is of limited use in psychiatry for three major reasons. First, it has only one-tenth morphine’s potency yet the two have similar addiction and physical dependence risk (240). Second, its short duration of action necessitates frequent meperidine dosing and this practice cycles through peaks and troughs in serum concentrations. Third, meperidine is metabolized to normeperidine, a toxic metabolite that causes CNS hyperexcitability that can manifest as seizure, anxiety, tremors, and myoclonus (241). Patients with impaired renal function are obviously susceptible to meperidine toxicity, but healthy individuals are also vulnerable because normeperidine accumulates with use greater than several days. Finally, naloxone, an opioid antagonist, cannot prevent or reverse overdose and it may even worsen CNS toxicity (33).

### Methadone

Methadone, along with dextropropoxyphene, is both an agonist to  $\mu$ -receptors and a weak, noncompetitive antagonist to NMDA receptors. Discovery of this unique dual action has led to increased use of methadone for the treatment of neuropathic pain, including phantom limb pain, and burn pain in the recent years (242–244). Methadone is also becoming increasingly used as a second-line agent in treating cancer pain unresponsive to conventional opioids (44). Traditional uses include management of severe, chronic pain, and suppression of withdrawal symptoms from heroin and morphine. For the latter reason, there is social stigma associated with methadone.

This schedule II controlled opioid has several advantages including its lack of active metabolites, its high lipid solubility, its excellent absorption after oral and rectal delivery, and its availability at low cost (45). Despite these advantages, the conversion schedule (i.e., dose and time course) between methadone and other opioids remains indeterminate. Confusion

arises from the fact that parenteral methadone is proposed, but not proven to be equianalgesic to morphine and traditional opioid conversion charts have underestimated the potency of methadone, leading to safety concerns (245). Another drawback to methadone is its long half-life because unpredictable drug accumulation at the beginning of a regimen carries a risk of respiratory depression. Myoclonus and electrocardiographic changes (e.g., QT prolongation and torsade de pointes) have been reported as well (246). Methadone is also increasingly being abused by recreational drug users and has been associated nationally with increase in overdoses and deaths. Because it does not lead to quick onset or significant euphoria, its substance abuse potential had been considered as low. Unfortunately, it can be hours before a user feels any effect, and by the time they have actually overdosed, no one is with them.

### Oxycodone (OxyIR, Oxycontin, Eth-Oxydose)

Oxycodone is a morphine derivative that is available as a generic short-acting form, a short-acting IR form (OxyIR), a controlled-release form (OxyContin), as well as several combination-analgesic products. Pure oxycodone products offer the advantage of not being limited by the potential for toxicity, which is associated with increasing doses of aspirin and acetaminophen. Its efficacy in managing neuropathic and somatic pain has been established, but OxyContin is only approved for management of chronic, moderate-to-severe pain (247).

OxyContin has high oral availability due to minimal first-pass metabolism. Easy access has historically led to its widespread abuse in the United States (248). This in fact has led the FDA to place a black box warning on the product, categorize it as a schedule II controlled substance, and order the discontinuation of the 160-mg tablets. Despite these problems with diversion, OxyContin is still a valuable medication with a fast onset and long duration of action—the apparent dichotomy of prompt yet sustained analgesia can be explained by the AcroContin delivery system, whereby oxycodone is released relatively quickly after ingestion and continues to be steadily released over the subsequent 12 hours. When dosed around the clock, it provides sustained serum levels through the night and potentially minimizes narcotic side effects often associated with peak serum drug levels. A relatively short half-life also allows for OxyContin to reach steady state in a short time period, thereby achieving its full analgesic potential within a day or two of treatment initiation. An additional benefit is that, unlike MS Contin, its absorption is independent of pH; this allows patients to take the opioid with or without food.

The short-acting IR form, OxyIR, can be used as premedication prior to physical therapy for patients whose pain level interferes with meaningful participation in therapeutic exercises. One-fourth to one-third the 12-hour dose of OxyContin can also be prescribed to treat breakthrough pain. If more than 2 rescue doses are needed during any 24-hour period, the OxyContin regimen should be titrated.

The liver extensively metabolizes oxycodone into oxycodone, which has even greater analgesic potency, and noroxycodone, a weak analgesic. Neither metabolite causes end-organ

toxicity. Efficacy and adverse events are believed to be similar for both OxyIR and OxyContin (249,250). Compared to morphine, they cause less nausea and vomiting but more constipation (251).

## Partial Agonists

### Buprenorphine (Buprenex, Subutex, Suboxone)

Buprenorphine, a mild-to-moderate analgesic, has been available via parenteral administration for many years. This partial agonist, with agonistic activity at  $\kappa$ - and  $\delta$ -receptors, became available to the United States in a sublingual form (Subutex) in 2002, and it was FDA approved for maintenance of opioid addiction (252). A TD delivery system for this medication can also be found in European markets. A recent review of various clinical studies concluded that oral, IV, intrathecal, and TD buprenorphine are all efficacious in managing neuropathic pain. Further research is however, required to develop guidelines for different syndromes (253). IV and oral administrations, additionally, have sustained antihyperalgesia effect in inflammatory models (254).

Slow dissociation from the  $\mu$ -receptor makes buprenorphine a long-acting agent. Fewer withdrawal signs occur because buprenorphine minimally affects GI motility and sphincter tone. It does not have an analgesic ceiling, but it can cause respiratory depression at high doses and this cannot be readily reversed with naloxone (255,256).

## MIXED AGONISTS-ANTAGONISTS

These analgesics are used for moderate to severe pain, but do not offer any superiority over opioid agonists. They have a lower respiratory depression risk compared to traditional agonists, but this benefit is minimal given that all agonist users build tolerance to respiratory depression over time. There are several disadvantages inherent to class, including an analgesic ceiling and the potential to precipitate a withdrawal syndrome among previous opioid users. It is nonetheless important to be somewhat familiar with several key members.

The prototype agent, pentazocine (Talwin, Talacen), is an antagonist at  $\mu$ -receptors and an agonist at  $\kappa$ - and  $\delta$ -opioid receptors. It is approximately equianalgesic to codeine on a milligram-per-milligram basis. Several different pentazocine combinations are available as shown in Table 65-17. It is unclear how pentazocine-containing medications can be best used in pain management. A pentazocine-methylphenidate combination—known by various street terms including *crackers*, *poor man's heroin*, and *T's and rits*—is subject to illicit use because the compound produces an effect similar to that of heroin mixed with cocaine. A new formulation, Talwin NX, blends pentazocine with naloxone to maintain analgesic effects but minimizes abuse.

Butorphanol tartrate (Stadol NS) is a mixed agonist-antagonist (i.e., agonist at  $\kappa$ -opioid receptors and a mixed agonist-antagonist at  $\mu$ -opioid receptors) that offers the flexibility of intranasal administration. Of note, widespread abuse of the

nasal spray led to its classification as a schedule IV controlled substance in the late 1990s. Butorphanol has not been widely used by physiatrists and there remains scant literature on its use in musculoskeletal pain (257,258). Instead, it has a niche in the general surgical setting, where it is used as a preoperative/postoperative sedative and analgesic, a supplement to balanced anesthesia, a conscious sedative, and a postanesthesia shivering suppressor. Additional applications include analgesia during labor, relief of moderate postpartum pain, and as a treatment for migraine headache.

### Relevant Side Effects and Drug Interactions

Before discussing opioid-related side effects, it is important to clarify three terms: tolerance, addiction, and dependence. *Tolerance* can be a double-edged sword. It potentially negatively affects treatment when an increasing amount of a drug is needed to produce a given therapeutic effect. Tolerance to side effects (other than constipation), however, is of obvious benefit. *Dependence* is the onset of withdrawal symptoms when a drug is abruptly removed. *Addiction* is the habitual use of a substance to achieve a certain effect—usually euphoria—that the patient perceives as pleasurable. Confusion of these terms has led to bias against the use of narcotic analgesics, particularly for nonmalignant pain. Fear of patient addiction is also the main reason why physicians tend to underprescribe narcotics (259). There is controversy as to whether psychological addiction actually develops in patients with chronic pain without a past history of substance abuse (260–262).

Health care providers may need to explain the concept of tolerance to patients and their families to quell the anxiety associated with increased narcotic requirement that often occurs after approximately 1 month of treatment. Tolerance begins after the first dose but does not become clinically apparent until the second or third week, and it generally lasts for up to 2 weeks after the regimen concludes. Since there is incomplete cross-tolerance among the different narcotic agents, analgesia can often be sustained with a schedule of opioid rotation (263). Finally, there is a notion that tolerance can be avoided altogether if opioid doses are matched with the patient's needs, such that there is no excess medication to cause euphoria and then tolerance.

Abrupt cessation of opioid therapy in a physically dependent patient can lead to withdrawal symptoms, which can sometimes be subtle and manifest only as complaints of mild, nonspecific muscle aches. Onset and duration of the withdrawal process correlates with the half-life of the specific drug, but autonomic symptoms can be blunted with the use of oral or TD clonidine, at a dose of 0.1 to 0.2 mg per day. Similar to tolerance, there is a notion that if doses are matched with the patient's needs then physical dependence will never develop. However, traditional teaching is that most patients who take opioids for more than 1 month will have some degree of physical dependence. In order to avert withdrawal symptoms in physically dependent patients, detailed guidelines have been developed for weaning patients off opioid treatment (264,265).

The overall side-effect profile for narcotic analgesics is relatively favorable, especially in the elderly population. Constipation is the most common narcotic side effect and it is also the only one to which tolerance will not develop over time. Since it can profoundly negatively affect patients' lives, the initiation of prophylactic bowel stimulants or osmotic agents should be strongly considered with opioid therapy. If constipation develops despite prophylaxis, it should be treated aggressively.

Other prevalent GI side effects include nausea with or without vomiting. Prophylaxis against nausea is not routinely employed because patients usually build tolerance to nausea over time. Treatment of nausea depends upon its etiology. If it is due to constipation, then the latter should be treated; in contrast, if nausea is due to a primary effect of the medication (i.e., stimulation of the chemotrigger zone), then prochlorperazine is the first-line agent for treatment of this. If the patient remains nauseous after addressing the above and other possible etiologies, agents such as haloperidol could be considered. If the patient additionally develops agitation, chlorpromazine would be an appropriate second-line agent of choice. Metoclopramide can be employed if the suspected etiology is gastric outlet obstruction, secondary to the antimotility effect of opioids. Nonoral adjuvant analgesics (e.g., IV indomethacin or IM ketorolac) may be more appropriate for patients suffering from narcotic-related nausea.

Patients on opioid therapy can also experience significant non-GI-related adverse events. Orthostatic hypotension, for example, can reach a degree where it limits rehabilitative transfer and ambulation training. Respiratory depression, manifested as reduced respiratory rate in the early stage, can also become severe enough to cause respiratory arrest. Habitual users are less likely than narcotic-naïve patient to suffer the extremes of either event because of a phenomenon known as *tolerance*, where patients adapt to a drug's effects over time. Evolving theories attribute receptor desensitization and receptor down-regulation to tolerance (266).

Opioids can induce a variety of additional side effects. For example, opioids can influence various hormones of the hypothalamus-pituitary-gonad system (267,268). Both acute administration and chronic use of opioids, in the absence of pain, can be immunosuppressive (269). Repeated administration may produce hyperalgesia (266,270,271). Potential CNS side effects include sedation and euphoria. Sedation can be countered using stimulants such as caffeine, dextroamphetamine, and methylphenidate. Euphoria is comparatively more problematic as it is the basis behind psychological addiction.

### Tramadol Hcl (Ultram); Tramadol Hcl and Acetaminophen (Ultracet)

#### Relevance to Physiatry

Tramadol is a centrally acting, synthetic analgesic with FDA approval for management of moderate-to-severe pain. It is a unique drug because it is not classified as a controlled substance (though its  $\mu$ -receptor binding affinity is similar to

codeine) and it has an additional mechanism of action akin to many antidepressants. Given the dual mechanism, tramadol can be an effective analgesic for both nociceptive and neuropathic pain (272). Randomized-controlled trials have demonstrated its efficacy in treating postherpetic neuralgia, phantom limb pain, diabetic neuropathy, and polyneuropathy of various etiologies (273–276). As for chronic nociceptive pain, the American College of Rheumatology (ACR) recommends tramadol for OA patients who failed to achieve adequate benefit from nonnarcotic analgesic medications (277). Finally, this weak opioid agonist can also be used to treat migraine, moderately severe episodic breakthrough pain and it has been studied in acute dental and surgical pain (278,279).

Ultracet contains 37.5 mg of tramadol and 325 mg of acetaminophen. Its exact role in pain management is evolving. Its advantages, like any other combination analgesics, are synergistic analgesia and reduced dose-dependent side effects (280). Only three randomized, placebo-controlled studies have been conducted to date using Ultracet and they show that it is as effective as and better tolerated than acetaminophen with codeine (at 300 mg per 30 mg) for chronic, nonmalignant low back pain, OA pain, and fibromyalgia (281–283). An ongoing randomized, multicenter is investigating Ultracet's efficacy in treating pain associated with rheumatoid arthritis (284).

The extended-release form, Ultram ER, has a convenient once-daily dosing schedule for managing chronic pain conditions. It is shown to have similar tolerability and effectiveness at relieving moderate to severe OA pain as the original tramadol (285).

All things considered, tramadol is potentially advantageous compared to NSAIDs and COX-II inhibitors because it does not cause GI bleeding or exacerbation of HTN or CHF (286). There may also be decreased tolerance to tramadol's therapeutic effect with chronic use in treatment of pain due to knee and hip OA (287,288).

### ***Mechanism of Action and Pharmacokinetics***

Tramadol has two complementary analgesic mechanisms including weak activation of  $\mu$ -receptors and pain impulse transmission modification, via weak inhibition of NE and serotonin reuptake. This compound can therefore be thought of as both a synthetic opioid and a TCA.

Tramadol has high bioavailability. Following oral administration, one-fifth of the drug is protein bound and it undergoes extensive first-pass hepatic metabolism. Onset of analgesia is apparent within 1 hour and a mean peak plasma concentration is reached within 1.5 to 2 hours. The liver demethylates and glucuronidates tramadol into several metabolites, only one of which have analgesic properties (289). All metabolites and the unchanged portion are renally excreted. Tramadol has a half-life of 6 hours and steady state is achieved within 2 days when it is taken four times daily.

### ***Preparations and Dosing***

Tramadol is available in the United States as 50-mg IR tablets. Extended-release tablets (Ultram ER in denominations of 100,

200, and 300 mg) recently became available in U.S. market. IV, IM, rectal, and subcutaneous preparations are available internationally.

The usual dosing range for IR tramadol is between 50 and 100 mg, every 4 to 6 hours. The maximum recommended dose is 400 mg daily. Dosing adjustments are recommended for patients older than 75 years old (<300 mg/day), with a creatinine clearance less than 30 mL/minute (administer every 12 hours, with a maximum daily dose of 200 mg), and a history of hepatic dysfunction. Patients with nonacute pain initiated on a starting dose of 50 mg every day, increased by one 50 mg dose every 3 days until the maximum daily dose is reached; this strategy minimizes side effects. Patients with acute pain can be treated with an initial 50-mg dose, followed by another 25 to 50 mg dose if adequate analgesia is not achieved within the first hour.

The starting dose for extended-release therapy is 100 mg daily, which can be increased at a rate of 100 mg/day for every 5 days. The recommended maximum dose is 300 mg/day but a daily dose of 400 mg has been safely prescribed for patients under 75 years old in several studies (290,291).

### ***Relevant Side Effects and Drug Interactions***

Nausea, drowsiness, and constipation are the most common side effects (292). The frequency of both is notably less than with traditional opioids. Vomiting, somnolence, abdominal pain, headache, dry mouth, dyspepsia, and vertigo have also been reported (280). Respiratory depression and pruritus are potential side effects associated with all opioids, but tramadol has a much lower risk of either incident (293). Serious, and rarely fatal, anaphylactoid reactions have occurred following the first tramadol dose; individuals with a history of anaphylactoid reactions to opioids may be at higher risk.

Seizure is a rare but significant side effect of tramadol. Caution should be exercised if tramadol is prescribed to patients with epilepsy, a seizure history or seizure risk factors (e.g., TBI, metabolic disorders, alcohol/drug withdrawal, and CNS infections). SSRIs or TCAs should not be prescribed with tramadol because they may further lower the seizure threshold. CNS depressants and MAOIs should be avoided as well because they pose risks of and hypertensive crisis, respectively. One should also be aware that carbamazepine markedly induces tramadol's metabolism, such that twice the usual tramadol dose might be needed.

Tramadol is a nonscheduled opioid and it has limited abuse potential because it rarely produces euphoria. However, abrupt cessation of therapy can lead to opioid withdrawal symptoms—though they may not as severe as with other opioids—and atypical withdrawal symptoms (e.g., hallucinations and paranoia) (294).

## **TD AND TOPICAL ANALGESIC MEDICATIONS**

The skin can be used to deliver medications locally, to an underlying target tissue, or systemically. Depending upon the

medication, delivery can be via an exogenous, disposable TD delivery system, or topical application of cream or ointment. While the terms *TD* and *topical* are often used interchangeably, TD delivery aims to achieve systemic therapeutic levels similar to those of oral administration and can be administered distal to the target site over an extended period of time. The fentanyl patch is an example of a true TD delivery system while topical NSAIDs, the topical NSAIDs patch Flector (topical diclofenac epolamine), and the lidocaine patch are examples of topical application.

TD delivery and topical application have become increasingly popular as it circumvents the unpredictability of GI tract absorption and hepatic first-pass metabolism. Topical medications can also achieve higher therapeutic concentration at local sites than do systemically administered medications.

All TD delivery systems comprise three elements: a backing, the active drug, and the adhesive. First-generation reservoir systems release active drug via a rate-limiting membrane. Second-generation matrix systems have the active drug embedded in polymer layers and are directly applied to the skin. Both systems deliver the active drug at a constant rate and thereby maintain constant drug-plasma level. This feature, in turn, extends the therapeutic activity for drugs with short half-lives and improves patient compliance by increasing the dosing interval.

An increasing number of medications will likely be delivered via the skin in the future as new mechanical enhancements are developed to increase TD topical permeability and allow patient-controlled administration. Iontophoresis is a currently available enhancement mechanism and various others (e.g., electroporation, sonophoresis, and microneedles) are being investigated (295–297).

Unfortunately, several factors limit TD and topical analgesic medication application. For one, significant contact dermatitis can occur among selected individuals. TD delivery and topical application are also not suitable for all medications. The efficacy of individual analgesic medications is further complicated by variables including humidity of the skin, ambient temperature, a drug's thermodynamic properties, and the target tissue's properties. The major disadvantage remains that most TD preparations (especially that of topical NSAIDs) have relatively short shelf lives, which makes mass production difficult.

The physiatrist should become familiar with TD delivery and topical application because they may encounter some of these medications in daily practice. A partial list of available TD medications classes includes analgesics, antibiotics, anticholinergics, antiemetics, and hormones. Aforementioned medications can also be delivered across mucous membranes using intranasal sprays, ophthalmologic solutions, and suppository.

Topical agents are widely available OTC but many TD medications are only available using a specialized pharmacy known as a *compounding pharmacy*.

## Individual Agents

EMLA, lidocaine, and Fentanyl patches have been discussed previously in this chapter.

## Diclofenac Epolamine (Flector Patch)

### Relevance to Physiatry

Although the international community has had significant experience with topical NSAIDs and they are reported to be well tolerated, particularly with respect to their lack of GI side effects associated (297), as of early 2008 Flector was the only topical NSAID approved in the United States.

The active ingredient in Flector patch is 1.3% diclofenac epolamine. It is indicated for minor sprains, strains, and contusions. Randomized controlled trials have also shown that it is effective in short-term treatment of symptomatic knee OA and epicondylitis (298,299).

An investigation of a combination preparation (heparin and lecithin with diclofenac epolamine) is underway and preliminary results suggest that this combination has superior anti-inflammatory, hemorrheologic, and antiedema effects for treating local trauma (300,301).

The FDA is also evaluating another topical NSAID (Pennsaid) which is available in Canada and several European countries for treatment of osteoarthritic pain (302).

### Mechanism of Action and Pharmacokinetics

The anti-inflammatory, analgesic, and antipyretic effects of diclofenac epolamine are similar to other NSAIDs. Flector patch reaches peak plasma level between 10 and 20 hours after application and the half-life of each patch is approximately 12 hours (303). Diclofenac avidly binds to plasma protein, is metabolized by the liver, and is then excreted along with urine and bile.

### Preparation and Dosing

Each Flector patch contains 180 mg of diclofenac epolamine in an aqueous base. The recommended dose is one Flector patch to the intact skin over the affected area bid (303).

### Relevant Side Effects and Drug Interactions

The most adverse effects of Flector patch are local skin reactions. Although diclofenac has similar side effect and drug-interaction profiles as other NSAIDs, the minimal serum medication levels associated with use in patch formulation lead to a lower risk of GI side effects (298).

## Capsaicin (Zostrix, Zostrix-Hp)

### Relevance to Physiatry

Capsaicin is a naturally occurring, reversible neurotoxin extracted from Solanaceae family plants (i.e., “hot” chili peppers) and is classified as a capsaicinoid. It is used by physiatrists to manage localized pain states (e.g., focal neuropathic pain) and joint arthralgias (e.g., knee and finger OA). Its use in OA is discussed in greater detail in Chapter 31. Topical capsaicin is FDA approved for the treatment of diabetic neuropathy, postherpetic neuralgia, along with pain due to OA and rheumatoid arthritis. Several studies found it to be beneficial for postoperative pain, trigeminal neuralgia, and cluster headache (95,304–308). There is also some scant literature on

management of complex regional pain syndrome type I and traumatic amputee neurogenic residual limb pain (309,310).

Capsaicin has recognizable efficacy in managing chronic musculoskeletal and neuropathic pain but is generally considered as an adjuvant analgesic. Study outcomes on the combined use of capsaicin and other topical medications have generally been favorable. For example, the combination of capsaicin (0.25%) and topical 3.3% doxepin was found to produce synergistic effects in neuropathic pain (20). A 2004 systematic review declared that capsaicin might be useful as an adjunct or sole therapy for patients with refractory pain (311).

Less direct physiatric applications of capsaicin include painful urological conditions, temporomandibular pain, oral mucositis, rhinitis, and psoriasis (16–20).

In addition to its clinical use, capsaicin has also become an integral part of pain management research (312,313). A human trigeminal sensitization pain model was developed to examine gender differences (314). In addition, basic science research suggests that an endogenous capsaicin-like substance is released in inflamed tissues and produces nociceptive neural impulses by acting on capsaicin receptors on sensory neurons (315).

### ***Mechanism of Action and Pharmacokinetics***

Analgesia is achieved by the binding to the vanilloid receptor-1 (VR1), which leads to the depletion of and inhibited accumulation of SP at the target site. SP is an endogenous neuropeptide produced by small-diameter, primary, sensory “pain” fibers; it is involved in the afferent transmission of pain impulse and stimulates immune cells (316,317). In addition to SP depletion, capsaicin also inhibits SP transport and *de novo* synthesis. The overall effect is a reversible sensory degeneration that leads to pain desensitization. Inflammation is also indirectly inhibited in the above process because inflammation has a neural component, which is referred to as *neurogenic inflammation*. The major proinflammatory players in this model are SP and related peptides (318). Capsaicin’s biochemistry is still under investigation (319,320).

### ***Preparations and Dosing***

Capsaicin is available under various trade names including 0.025% (Zostrix) and 0.075% (Zostrix-HP) topical cream preparations that are to be applied three to four times daily. Patients should be initiated on the lower-concentration preparation to minimize early, unfavorable effects.

### ***Relevant Side Effects and Drug Interactions***

Transient application site stinging and burning, caused by activation of C fibers, is experienced by up to 50% of patients at the onset of treatment, particularly with the higher potency formulation. Capsaicin studies have on average incurred 13% participant withdrawal rate due to intolerable burning (311). Capsaicin is not deemed appropriate for acute musculoskeletal pain for this reason though this side effect usually remits after the first few days (321). This phenomenon is attributed to depletion of SP with repeat application. Cough is another possible

adverse effect. No adverse effect upon nerve function and no drug interactions have been documented to date (322).

## **ANTICOAGULANTS**

### **Relevance to Physiatry**

These medications are primarily used as prophylaxis against excessive clot formation. In general, they affect the function and synthesis of clotting factors, thus reducing the tendency toward clot propagation and the risk of developing or extending a deep venous thrombosis (DVT), or pulmonary/cerebral embolus. Patients at risk for developing thromboembolic phenomena are frequently encountered in the rehabilitative setting, and include those with SCI, stroke, multiple trauma, as well as hip and knee arthroplasties. Risk reductions, including anticoagulation and conservative means to stimulate blood flow in the legs, such as with external compression devices, are warranted in appropriate patients. Patients who have suffered a cerebral thromboembolic event, those with proximal DVT, and pulmonary emboli are generally treated similarly (323–330).

Anticoagulants can be classified into heparin and coumarin groups. The heparin group is administered parenterally and includes unfractionated heparin (UFH), low molecular weight heparin (LMWH), and heparinoids (including fondaparinux and danaparoid). IV full-dose UFH had been the mainstay of initial treatment of acute thromboembolic phenomena, such as DVT, pulmonary embolus (PE), as well as unstable angina and non-Q-wave myocardial infarction (MI), and requires inpatient therapy. Currently, it is acceptable to initiate therapeutic anticoagulation utilizing subcutaneous LMWH or certain heparinoids in appropriate patients, even on an outpatient basis in those with DVT, and even possibly PE (323–337). Although subcutaneous fixed low-dose UFH can be used for prophylaxis, LMWH and some heparinoids are more effective and are associated with a lower risk of hemorrhage (338–347). Heparinoids can also be used for thromboembolism prophylaxis or treatment in the presence of heparin-induced thrombocytopenia (348–351).

Warfarin is by far the most commonly used coumarin medication. Its use in DVT prophylaxis following hip or knee arthroplasty has been well established (352,353). Although its efficacy in preventing DVT in orthopedic patients may be somewhat less than that of LMWH, it is the mainstay of maintenance treatment of thromboembolism following initial heparin treatment. Another important indication for oral anticoagulation is stroke prophylaxis, especially in the presence of atrial fibrillation (AF) (353–355). Specifically, it has been shown that oral anticoagulation is associated with a significant reduction of stroke risk, and that it is more efficacious than aspirin in preventing stroke in the setting of AF (355).

Whenever an anticoagulated patient is undergoing physical and/or occupational therapy, it is prudent to include this information in the therapy prescription so that the therapist can take appropriate precautions to prevent falls and injuries.

This also alerts the therapist to monitor closely and report potential signs of bleeding, such as a newly swollen joint, as this may represent a hemarthrosis.

### Mechanism of Action and Pharmacokinetics

Heparin and its derivatives affect key reactions involved with thrombosis and stable clot formation. Low-dose UFH and LMWH primarily prevent the conversion of prothrombin to thrombin (factor II) via inactivation of factor Xa. At higher doses, heparin can prevent fibrinogen-to-fibrin conversion by inactivation of thrombin and also prevents stable fibrin clot formation. After subcutaneous injection, activity onset is rapid, with peak plasma levels at about 4 hours. Metabolism occurs in the liver and the reticuloendothelial system.

Warfarin interferes with vitamin K, by inhibiting hepatic coagulation factor II, VII, IX, and X synthesis. Its effect is detectable once the baseline level of these factors already in circulation starts to be depleted by metabolic degradation. After oral administration, the maximal plasma concentration is between 1 and 9 hours. Almost all of the medication (97%) is bound to plasma albumin. The initial effect is apparent in 24 hours, but the peak effect occurs between 3 and 4 days and lasts for 4–5 days. It is metabolized in the liver and has a half-life of around 2½ days.

### Preparations and Dosing

Both UFH and LMWH are mucopolysaccharides derived from porcine intestinal mucosa. LMWH is derived from UFH by depolymerization and possesses a higher ratio of antifactor Xa to antifactor IIa activity than pure UFH. Therefore, it is purported to have a lower incidence of bleeding complications versus UFH. The molecular size of both heparin classes does not permit oral administration as they would not be readily absorbed from the GI tract. Therefore,

they are currently administered either by deep subcutaneous injection or intravenously. Modified, orally active forms of heparin are being studied (356). Although it is necessary to monitor the activated partial thromboplastin time (aPTT) during full-dose IV UFH therapy, it is not necessary to do so during standard fixed low-dose UFH and LMWH therapy since this index is essentially unaffected. However, it is important to note that full therapeutic doses of LMWH can affect the aPTT.

These medications are generally utilized short term, in inpatient as well as outpatient settings (323–326,331,338–347). For prophylaxis, they are used based upon diagnosis or until risk of thromboembolism has diminished. In the event of acute PE or DVT, they are administered at therapeutic dosages concomitantly with warfarin, which is initiated within the first 3 days. Once a therapeutic INR is achieved, typically within 5 to 7 days, heparin is discontinued, while warfarin therapy is maintained for a variable time period depending on the underlying condition. In certain cerebrovascular accidents (CVAs) or MIs, antiplatelet agents are used in lieu of warfarin. Dosages and indications for subcutaneous administration of heparins and derivatives are shown in Table 65-18.

Warfarin sodium (Coumadin, Panwarfin) is the most commonly utilized oral anticoagulant. In those rare cases when oral administration is not feasible, warfarin may be given intravenously. Dosage is individualized and based on monitoring its efficacy by regular PT assessment. Because of significant variability in thromboplastin reagents used in making these assessments among laboratories, a common standardized scale, the (INR), was developed to allow for more comparable monitoring of efficacy regardless of the reagents used. An INR of 2.0 to 3.0 is generally recommended for both prophylaxis and thromboembolism treatment. The effectiveness of

**TABLE 65.18 Heparin and Heparin Derivatives Administered Subcutaneously**

Generic (Trade) Name	Type	Typical Dosage and Indications (FDA Approved and Unapproved)
Heparin sodium	UFH	DVT prophylaxis: 5,000 units q8–12 h; lower doses in geriatric patients
Dalteparin (Fragmin)	LMWH	DVT prophylaxis: 5,000 units qd following orthopedic surgery (FDA approved only for THA) or immobilization caused by acute illness; 2,500 units qd following abdominal surgery or for other conditions (not FDA approved). DVT/PE treatment: 200 units/kg qd
Enoxaparin (Lovenox)	LMWH	DVT prophylaxis: 30 mg q12h (approved for THA/TKA; unapproved for SCI and MT) or: 40 mg qd (approved alternate dosing following THA, immobilization because of medical illness or following abdominal surgery). DVT/PE treatment: 1 mg/kg q12h, or 1.5 mg/kg qd
Tinzaparin (Innohep)	LMWH	DVT/PE treatment: 175 anti-Xa units/kg qd until therapeutic anticoagulation with warfarin. Also unapproved indication for DVT prophylaxis: 4,500 units qd following orthopedic surgery or 3,500 units qd following general surgery
Fondaparinux (Arixtra)	Synthetic factor Xa inhibitor	DVT prophylaxis: 2.5 mg qd (approved for THA/TKA and hip fracture surgeries, as well as following abdominal surgery) DVT/PE treatment: 5 mg qd if <50 kg, 7.5 mg qd if 50–100 kg, 10 mg qd if >100 kg.
Desirudin (Iprivask)	Selective thrombin inhibitor	DVT prophylaxis following THA: 15 mg q12h

anticoagulation within this range is essentially equivalent to that of higher dosages, yet with fewer hemorrhagic events (357). In contrast to biological heart valve replacement, a higher INR (2.5 to 3.5) is suggested for mechanical heart valves. For the clinician, it can sometimes be challenging to determine the specific dosage of warfarin that will maintain the INR of a given patient within the therapeutic range. However, there has been recent association of specific genotypes, particularly *CYP2C92* and *CYP2C93* and *VKORC1*, with variability in warfarin dosing efficacy in certain individuals, which may lead to the development of more “personalized” dosing regimens with a reduction of unpredictability in achieving therapeutic INRs (338,358–366).

Warfarin’s usual starting dose is from 5 to 10 mg qd. Larger loading doses should be avoided, given the increased risk for hemorrhage. It is also prudent to start with lower loading doses in the elderly or debilitated or in those who are known to be sensitive to warfarin. Oral anticoagulation is usually initiated at the time of heparin treatment, is overlapped with it for about 4 to 5 days in order for the INR to increase to 2.0–3.0, and is then continued alone. For instance, the common practice in treating orthopedic patients is to discontinue the anticoagulant before discharge home or when the patient is fully ambulatory. However, there is evidence that supports longer treatment in order to further reduce DVT risk (367,368).

### Relevant Side Effects and Drug Interactions

Adverse effects of greatest concern with anticoagulants are hemorrhage, most commonly presenting as bruising, petechiae, epistaxis, GI, or urinary tract bleeding. Extreme caution should be exercised in those at increased risk for bleeding, including those who are already taking antiplatelet agents.

A potential problem specific to heparin is heparin-induced thrombocytopenia which occurs from either a direct effect on platelets or by an immunologic response. Thus, it is important to monitor CBCs, especially at the start but also at regular intervals during treatment. Also, there have been reports of spinal epidural hematomas with ensuing paralysis following use of LMWH in patients who have or very recently had epidural catheters or punctures. Therefore, the manufacturers of LMWH have issued warnings against administering these drugs within specific times before and following procedures involving epidural invasion. Other adverse effects that may occur include local irritation (especially with deeper injections; thus the need to avoid IM injection) and hypersensitivity reactions, especially with pork allergies.

A relatively rare but potentially hazardous reaction associated with warfarin use is skin necrosis, which may develop in susceptible individuals such as those patients with protein C deficiency because there is normally local thrombosis that occurs within the first few days of initiating the drug. The concurrent administration of heparin for the first 5 to 7 days of anticoagulation reduces the risk of this reaction.

Many drugs can alter the therapeutic efficacy of warfarin. Those that may increase the PT include APAP, amiodarone, ASA, NSAIDs, phenytoin, sulfonamides, and thyroid supple-

ments. Those that can decrease the PT include adrenocorticoids, antacids, antihistamines, carbamazepine, haloperidol, and vitamin C. Others, including diuretics and H<sub>2</sub> blockers, may cause either an increase or decrease in the PT.

## ANTITHROMBOTICS

### Relevance to Physiatry

Antithrombotics (i.e., antiplatelet drugs, because of their primary effect of inhibiting platelet aggregation) have widespread use in patients with cardiovascular illness. The most widely used agent in this group is ASA, which, in appropriate patients, has been associated with significant reductions stroke and MI risks (369–371). It has also been suggested that ASA given early after ischemic CVA onset can help to reduce morbidity and mortality (372,373). However, other antithrombotic drugs such as clopidogrel, cilostazol, ticlopidine, and dipyridamole play an important role. In fact, there is evidence that they can be more effective than ASA in stroke prevention. This had been demonstrated with ticlopidine, but the risk of potentially serious adverse effects has limited its use (374). In contrast, clopidogrel, a drug similar to ticlopidine, has been reported to be as effective yet with a better safety profile (375–380). The combined use of dipyridamole and ASA is superior for stroke prevention compared to ASA alone (381). Ongoing trials are comparing these agents to one another as well as in combination to determine greatest efficacy in cardiovascular disease prevention (382–386).

Cilostazol is a phosphodiesterase III inhibitor that improves walking distance and exercise tolerance in patients with peripheral vascular disease and may also improve lipid profiles (387–390).

### Mechanism of Action and Pharmacokinetics; Preparations and Dosing; Relevant Side Effects and Drug Interactions

See Table 65-19.

## ANTHYPERLIPIDEMIC MEDICATIONS

### Relevance to Physiatry

The importance of antihyperlipidemic agents in therapy and risk reduction of cardiovascular disease has been well established (391–394). The reduction of serum lipids, including cholesterol and triglycerides, is associated with decreased cardiac morbidity from atherosclerotic cardiovascular disease. More recent evidence suggests that these medications can reduce ischemic stroke risk in the presence of cardiovascular risk factors and may also play a neuroprotective role during CVA (391–398).

### Mechanism of Action and Pharmacokinetics

These drugs can be classified into *fibrates* and *HMG-CoA reductase inhibitors*, known popularly as the *statins*. The latter

**TABLE 65.19 Antiplatelet Agents**

Generic (Trade) Name	Mechanism of Action	Dosing (mg)	Other Properties, Relevant Side Effects, and Drug Interactions
Aspirin (ASA)	Inhibits thromboxane A-2 synthesis and thus ability of platelet aggregation	81–325 PO qd	Regular, buffered, and enteric coated; avoid using with ticlopidine
Ticlopidine (Ticlid)	Interferes with platelet membrane function, reducing aggregation by impeding ADP-induced platelet-fibrinogen binding. Effect persists for the life of the platelet.	250 PO bid (as with ASA, higher doses associated with greater likelihood of adverse effects, but antithrombotic effect is the same) (289)	Risk of severe hematological reactions such as neutropenia, agranulocytosis, or thrombotic thrombocytopenic purpura (TTP), especially in the first 3 months of therapy. Need to monitor CBC biweekly during this time. Should not be used in severe liver impairment. Phenytoin and propranolol levels might be increased by ticlopidine
Dipyridamole (DP) (Persantine)	Increases platelet cAMP; thus less adherence, aggregation, and enzymatic activity	75–100 PO qid	Vasodilation, thus caution in those with hypotension; diarrhea, vomiting, flushing, or pruritus
Aggrenox (DP+ASA)	See earlier	1 cap (200 mg DP/25 mg ASA) PO bid	
Clopidogrel (Plavix)	Interferes with platelet membrane function, reducing aggregation by impeding ADP-induced platelet-fibrinogen binding. Effect persists for the life of the platelet.	75 PO daily	May cause TTP, usually in first 2 wk
Cilostazol (Pletal)	Phosphodiesterase III inhibitor	100 PO bid	Contraindicated in CHF; reduce dose when used with cytochrome P450 3A4 and 2C19 inhibitors

primarily lower serum low-density lipoprotein (LDL) cholesterol levels, whereas the fibrates lower serum triglyceride and very low density lipoprotein (VLDL) cholesterol levels. All these medications have the beneficial effect of elevating serum high-density lipoprotein (HDL) cholesterol. Other agents

include bile acid sequestrants as well as ezetimibe, an inhibitor of GI absorption of cholesterol.

### Preparations and Dosing

See Table 65-20.

**TABLE 65.20 Antihyperlipidemic Medications**

Generic (Trade) Name	Typical Oral Dose (mg)
<b>HMG-CoA Reductase Inhibitors</b>	
Atorvastatin (Lipitor)	10 qd, max 80 qd
Fluvastatin (Lescol, Lescol XL)	20 h, max 80 qd (XL) or 40 bid
Lovastatin (Mevacor, Altoprev [an extended-release medication])	20 qPM, max 80 qd (dose may be divided in 2 per d), extended release: 10 qPM, max 60 qPM
Pravastatin (Pravachol)	10 qd, max 40 qd
Rosuvastatin (Crestor)	5 qd, max 40 qd
Simvastatin (Zocor)	20 qPM, max 80 qd
<b>“Fibrate” Medications</b>	
Clofibrate (Atromid-S)	1,000 bid
Fenofibrate (Tricor)	67 qd, max 200 qd; taken with a meal
Gemfibrozil (Lopid)	600 bid before meals
<b>Bile Acid Sequestrants</b>	
Cholestyramine (Questran, Prevalite)	4 g qd or bid
Colesevelam (WelChol)	3 tabs bid or 6 tabs qd (taken with meals)
Colestipol (Colestid)	5–30 g/d, once or in divided doses
<b>Other</b>	
Ezetimibe (Zetia)	10 qd

### Relevant Side Effects and Drug Interactions

Potential concerns associated with these drugs include myopathy and rhabdomyolysis, especially when both classes are used together, and liver dysfunction. The fibrates in particular can also elevate PT results in patients receiving warfarin.

## CARDIOVASCULAR MEDICATIONS

Medications that affect the cardiovascular system are frequently encountered in the rehabilitative setting, especially in the elderly. It is not uncommon for the physiatrist to adjust these medications, especially while the patient is on an inpatient rehabilitation unit. Because these medications can have such a profound impact on the patient's medical status and general well being, it is important for the physiatrist to have a basic knowledge of the types of medications used, their indications, and their effects.

### Alpha-blockers: $\alpha$ -1 Adrenergic and $\alpha$ -2 Adrenergic Antagonists Relevance to Physiatry

The primary use of these medications, especially  $\alpha$ -1 adrenergic blockers, is for the treatment of HTN and prostate-related bladder outlet obstruction, especially  $\alpha$ -1 adrenergic blockers. They are also used for the control and prevention of vascular manifestations of autonomic dysreflexia (399). A nonselective  $\alpha$ -blocker such as phenoxybenzamine can also be effective in RSD because it affects both types of  $\alpha$  receptors, thus leading to a chemical sympathectomy. It is usually best to initiate these drugs at bedtime given the frequent occurrences of orthostatic hypotension and reflex tachycardia during the first few days of initiating treatment (i.e., the first-dose phenomenon) and

the fact that postural hypotension can also occur following rapid increases in dosage, during the established use of these medications, or following the addition of a second antihypertensive.

Alpha-2 selective blockers (e.g., yohimbine [Yocon]) might help with erectile dysfunction, diabetic neuropathy, and postural hypotension (400,401).

### Mechanism of Action and Pharmacokinetics

These medications block  $\alpha$ -1 and/or  $\alpha$ -2 adrenergic receptors. Selective  $\alpha$ -1 receptor blockers inhibit vasoconstriction, resulting in decreased peripheral vascular resistance and a subsequent decrease in BP. They also reduce resistance to urinary outflow by inhibiting smooth muscle contractions at the base of the urinary bladder. In contrast, selective  $\alpha$ -2 blockers and nonselective blocking agents indirectly cause the release of NE from peripheral sympathetic nerve endings, thus increasing overall sympathetic outflow, and leading to subsequent elevations in heart rate (HR) and BP.

### Preparations and Dosing; Relevant Side Effects; and Drug Interactions

See Table 65-21.

### Alpha-2 Agonists

#### Relevance to Physiatry; Mechanism of Action; and Pharmacokinetics

These medications are indicated for HTN, either alone or in combination with other medications. They may be used in acute autonomic dysreflexia refractory to other measures and also in the prevention of its recurrence (399). Because of their centrally acting mechanism (stimulation of  $\alpha$ -2 adrenergic receptors), they may cause drowsiness, a definitely untoward

**TABLE 65.21 Cardiovascular Medications Acting on the Sympathetic Nervous System**

Generic (Trade) Name	Typical Dose (mg)	Other Properties and Side Effects
[Alpha agonists]		
Clonidine hydrochloride (Catapres, Catapres-TTS)	Oral: 0.1 bid–2.4 mg/d patch: 0.1–0.3/d—change q wk	Renally metabolized; also used to blunt autonomic symptoms from narcotic withdrawal
Guanfacine hydrochloride (Tenex)	0.5–1.0 PO/d–3.0/d	Taken H/S to avoid daytime somnolence; renal metabolism
Guanabenz acetate (Wytensin)	4 PO bid and increased prn by 4–8/d up to 32/d	Hepatically metabolized
Methyldopa (Aldomet)	250 PO bid up to 3,000/d	First metabolized in the brain to methyl-NE, which activates $\alpha$ -2 receptors; parenteral form also available
Tizanidine (Zanaflex)	4–8 PO q6–8 h, max of 36 for every 24 h for spasticity control	Reported to have a much less tendency than clonidine for lowering of BP, thus not used for HTN
[ $\alpha$ -1 antagonists]		
Doxazosin (Cardura)	Start 1 PO qd; maximum 16 PO qd	If peripheral edema, can switch to Minizide (prazosin/polythiazide), 1 tab PO bid
Prazosin (Minipress)	Start 1 PO bid-tid; maximum 40 PO qd	
Tamsulosin (Flomax)	BPH: 0.4 PO qd; maximum 0.8 PO qd	
Alfuzosin (Uroxatral)	BPH: 10 qd	Reportedly less postural hypotension compared to the other $\alpha$ -blockers
Terazosin (Hytrin)	Start 1 PO qH/S; maximum 20 PO qd	
		Not available in combination with a diuretic

effect when attempting to objectively monitor the progress of a patient with altered mental status (e.g., early TBI or CVA) and therefore can interfere with rehabilitation. Clonidine and especially the newer  $\alpha$ -2 agonist tizanidine (Zanaflex) are also useful in treating spasticity in various patients, including those with SCI, TBI, multiple sclerosis, and CVA (402–408). TD or intrathecal clonidine may be of benefit in RSD pain (409,410).

### Preparations and Dosing

See Table 65-21.

### Relevant Side Effects and Drug Interactions

Dry mouth, sedation, various GI symptoms, and orthostatic hypotension are the most common side effects. Rebound HTN may occur with their sudden discontinuation. Major drug interactions include potentiation of the action of CNS depressants, attenuation of the hypotensive effect of TCAs, and additive cardiovascular side effects with other cardiovascular medications.

## Angiotensin-Converting Enzyme Inhibitors (ACEIs) and Angiotensin II Receptor Blockers

### Relevance to Psychiatry

These medications are commonly encountered in hypertensive and/or cardiac rehab patients. They exert a renal-protective effect in diabetics and are useful in reducing the risk of recurrent CVA (411–416). An advantage of these classes of medications is their relative lack of cardiovascular side effects compared to other agents.

### Mechanism of Action and Pharmacokinetics

ACEIs prevent the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor and adrenal stimulator. The overall effect is a reduction in systemic vascular resistance with subsequent lowering of BP and cardiac output improvement. The hypotensive effects of angiotensin II receptor blockers (ARBs) occur via selective blocking of the binding of angiotensin II to specific AT receptors especially in vascular smooth muscles and adrenal glands. Medications of this class are well absorbed from the GI tract and are well tolerated. They vary in onsets, peaks, and durations of action, which is reflected in their recommended dosage.

### Preparations and Dosing

See Table 65-22.

### Relevant Side Effects and Drug Interactions

These medications are generally well tolerated with rare serious adverse reactions. Side effects can include skin rash, neutropenia, impaired renal function (especially if there is preexisting impairment), GI discomfort, and a nonproductive cough due to an alteration in bradykinin production. Renal function should be monitored, especially in the elderly with poor oral fluid intake. ACE inhibitors can act synergistically with diuretics or other antihypertensives. Hyperkalemia can occur when

drugs that can elevate serum potassium concentrations (such as potassium supplements or potassium-sparing diuretics) are used with ACEIs and ARBs. Adverse effects of ARBs are generally minor and rare.

## ANTIARRHYTHMIC MEDICATIONS

### Relevance to Psychiatry

This group is likely to be encountered in patients undergoing cardiac rehabilitation or those who have a pertinent cardiac history and undergoing inpatient rehabilitation.

### Preparations and Dosing

See Table 65-23.

### Relevant Side Effects and Drug Interactions

The most common antiarrhythmic medication side effects include cardiac rhythm disturbances, hypotension, and GI disturbance. Since various drug interactions are possible, it is important for the psychiatrist to consider this whenever a new medication is added.

### Beta-Blockers

#### Relevance to Psychiatry

The psychiatrist should understand the reason(s) for which a patient is on a  $\beta$ -blocker. This is especially important following MI or with cardiac arrhythmias. During the second phase of a three-phase cardiac rehab program, a therapeutic exercise program of appropriate intensity for a patient on  $\beta$ -blockers is based on a percentage of the symptom-limited HR or on the maximum work load performed on an exercise stress test rather than being based on absolute HR (417). Beta-blockers tend to impair a patient's exercise tolerance.

Beta-blockers are especially used for HTN, angina pectoris, and arrhythmias. More recently, some of the  $\beta$ -blockers have been used in selected patients with compensated CHF (418,419). In addition,  $\beta$ -blockers are also used for migraine headaches, heightened metabolic turnover states, such as thyrotoxicosis, tremors of various etiologies, and may be of benefit in treating aggression such as that associated with TBI (420–425).

### Mechanism of Action

These medications bind with varying affinities to  $\beta$ -1 and  $\beta$ -2 adrenergic receptors. Those having a predominant  $\beta$ -1 receptor affinity are referred to as  $\beta$ -1 selective or cardio selective as this receptor is primarily cardiac. The therapeutic effect therefore is to decrease HR and myocardial contractility, which contributes to decreasing myocardial oxygen demand in coronary artery disease and leads to BP reduction in certain hypertensive patients. Others  $\beta$ -blockers are nonselective since they demonstrate essentially equal affinities for both  $\beta$ -1 and  $\beta$ -2 receptors. There are also  $\beta$ -2 selective compounds; however, they are not clinically relevant because blockade of the  $\beta$ -2 receptors (mostly located in bronchiolar smooth muscles) causes bronchoconstriction. Some also possess mild  $\beta$ -mimetic or

**TABLE 65.22 ACEIs and Angiotensin II Receptor Blockers**

Generic (Trade) Name	Oral Dose (mg)
<b>Angiotensin-Converting Enzyme Inhibitors</b>	
Benazepril (Lotensin)	HTN: 10 qd, up to 80 daily
Captopril (Capoten)	HTN: 25 bid-tid, up to 450 daily CHF: 6.25–12.5 tid LV dysfunction post MI: 12.5 tid to 50 tid Diabetic nephropathy: 25 tid
Enalapril (Vasotec)	HTN: 5 qd/bid, up to 40 daily CHF: 2.5 qd/bid, up to 40 daily
Fosinopril (Monopril)	HTN: 10 qd, up to 80 daily
Lisinopril (Prinivil, Zestril)	HTN: 10 qd, up to 40 daily CHF: 5 qd, up to 20 daily
Moexipril (Univasc)	HTN: 7.5 qd, up to 30 daily
Perindopril (Aceon)	4 qd up to 16 daily
Quinapril (Accupril)	HTN: 10 qd, up to 80 daily CHF: 5 bid, up to 20–40 daily
Ramipril (Altace)	HTN: 2.5 qd, up to 20 daily Reduction in risk of myocardial infarction, stroke, and death from cardiovascular causes: initial 2.5 qd for 1 wk, 5 qd for the next 3 wk, then up to 10 qd CHF post-MI: 2.5 bid up to 5 bid
Trandolapril (Mavik)	HTN: 1 qd, up to 4 daily CHF post-MI or LV dysfunction post-MI: initially 1 qd to 4 qd
<b>Angiotensin II Receptor Blockers<sup>a</sup></b>	
Candesartan (Atacand)	HTN: 16 qd, max 32 qd CHF: 4 qd to 32 qd
Eprosartan (Teveten)	HTN: 600 qd, max 800 qd (in single or divided bid)
Irbesartan (Avapro)	HTN: 150 qd, max 300 qd Diabetic nephropathy: 300 qd
Losartan (Cozaar)	HTN: 50 qd, max 100 qd Diabetic nephropathy: 50 qd to 100 qd
Olmesartan (Benicar)	HTN: 20 qd, max 40 daily # 30
Telmisartan (Micardis)	HTN: 40 qd, max 80 qd
Valsartan (Diovan)	HTN: 80 qd, max 320 qd CHF: 40 bid, max 320 qd (in divided doses)
<b>Direct Renin Inhibitor</b>	
Aliskiren (Tekturna)	HTN: 150 to 300 qd
<b>Selective Aldosterone Receptor Antagonist</b>	
Eplerenone (Inspra)	HTN: 50 qd, max 50 bid CHF post-MI: start 25 qd, target 50 qd

<sup>a</sup>Starting dosage should be ½ in volume-depletion.

α-1 antagonistic activity, which facilitates cardiac stimulation while blocking systemic effects of excess catecholamines.

### Preparations and Dosing

See Table 65-24.

### Relevant Side Effects and Drug Interactions

Adverse effects that can interfere with rehabilitation include orthostatic hypotension, bradycardia, and chronic obstructive pulmonary disease (COPD), asthma, or CHF exacerbation. Fatigue, sleep disturbance, and depression may also occur. Sudden medication discontinuation may exacerbate angina because of increased catecholamine sensitivity that may develop during prolonged treatment.

NSAIDs, phenytoin, and phenobarbital can alter the effects of β-blockers. Antihypertensives and antiarrhythmics should be used cautiously if given with β-blockers.

### Calcium Channel Blockers

#### Relevance to Psychiatry

These medications are commonly encountered in the psychiatric setting given their efficacy and convenient dosing (especially the controlled- and sustained-release preparations) for HTN and angina. The IR forms, although useful in various clinical situations, have become less popular because of adverse outcomes reportedly related to their use (426). This especially applies to SCI patients with autonomic dysreflexia for which nifedipine had been commonly given

**TABLE 65.23 Antiarrhythmic Medications**

Examples	Typical Oral Dosages (mg) and Arrhythmia Indications
<b>Class I<sub>A</sub></b> Quinidine gluconate (Quinaglute, Quinalan, Quinate); quinidine sulfate (Quinidex, Quinora); procainamide (Procanbid, Pronestyl); disopyramide (Norpace, Norpace CR); moricizine (Ethmozine)	<b>Electrophysiologic effect: blockage of sodium channels</b> Prevention of AF/flutter and PVCs, 324–648 q8–12 h; AF/flutter, 200–400 q6–8 h (IR) or 300–600 q8–12 h (ER); ventricular dysrhythmias, 250–625 q3h (IR) or 500–1,250 q6h (SR) or 500–1,000 q12h (Procanbid); ventricular dysrhythmias 400–800 per 24 h (q6h if IR or q12h if ER); 200 q8h, max of 900 per 24 h
<b>Class I<sub>B</sub></b> Lidocaine (Xylocaine, Xylocard); mexiletene (Mexitol); tocainide (Tonocard)	<b>Electrophysiologic effect: blockage of sodium channels</b> VT/VF, monitored IV dosage; ventricular dysrhythmias, 200 q8h, max 400 per 24 h; ventricular dysrhythmias, 400 q8h, max 2,400 per 24 h
<b>Class I<sub>C</sub></b> Flecainide (Tambocor); propafenone (Rhythmol)	<b>Electrophysiologic effect: blockage of sodium channels</b> PSVT or PAF: 50 q12h, max 300 per 24 h or sustained VT: 100 q12h, max 400 per 24 h; PSVT, PAF, sustained VT: 150 q8h, max 300 q8h
<b>Class II</b> Acebutolol (Sectral); propranolol (Inderal, Inderal LA); sotalol (Betapace, Betapace AF)	<b>Electrophysiologic effect: blockage of <math>\beta</math> adrenergic receptors</b> Ventricular dysrhythmias, 200 bid, max 1,200 bid; 10–30 tid–qid; ventricular dysrhythmias (Betapace) or AF/flutter (Betapace AF), 80 bid, max 640 per 24 h
<b>Class III</b> Amiodarone (Cordarone, Pacerone) bretylium (Bretylol); dofetilide (Tikosyn); sotalol (see earlier)	<b>Electrophysiologic effect: prolongation of membrane depolarization</b> Ventricular dysrhythmias, 800–1,600 qd for 1–3 wk, then 600–800 qd for 1 month, then 400 qd; monitored IV dosage; AF/flutter, 0.5 bid; see above
<b>Class IV</b> Verapamil (Calan, Calan SR, Covera-HS, Isoptin)	<b>Electrophysiologic effect: blockade of calcium channels</b> PSVT or RVR in AF, 240–480 per 24 h divided tid–qid

sublingually, a practice that should be avoided. Predominant side effects include orthostatic hypotension, peripheral edema, and headache. The physiatrist should be careful in ordering physical therapy modalities (e.g., whirlpool or Hubbard tank) that can accentuate the vasodilation in a patient taking a CaCB or other vasodilator. Concomitant use of other antihypertensives or antiarrhythmic should be done cautiously. Although grapefruit juice can enhance the effect of CaCBs, this is not usually of clinical significance unless the patient is on the previously popular grapefruit fad diet.

### Mechanism of Action and Pharmacokinetics

These drugs inhibit the entry of  $\text{Ca}^{2+}$  ions into the myocardial, sinoatrial, AV, and vascular smooth muscle cells by binding to specific voltage-sensitive channels in the cell membrane. This results in multiple cardiovascular effects. One of these is to reduce the strength of myocardial contraction. Another is to relax the arterial smooth muscles in the coronary arteries and peripheral arterioles. This leads to improved coronary blood flow and decreased peripheral vascular resistance with systemic BP reduction. Finally, pacemaker cell depolarization is impaired with a resultant slowing of cardiac conduction.

### Preparations and Dosing

See Table 65-25.

### Relevant Side Effects and Drug Interactions

Side effects most commonly relate to vasodilatation and include dizziness, orthostatic hypotension, reflex tachycardia, headache,

and edema. Coughing, GI disturbances, and bradyarrhythmias (especially in diseases affecting sinoatrial and AV nodes) can occur. Concomitant use with  $\beta$ -blockers is usually well tolerated, but sometimes leads to hypotension, CHF, or cardiac dysrhythmias. CaCBs may elevate serum digoxin and levels of other medications metabolized via the cytochrome P-450 system.

### Cardiac Glycosides

#### Relevance to Physiatry

Cardiac glycosides include digitalis, digoxin, digitoxin, and deslanoside, and are primarily used for mild to moderate CHF and ventricular rate control in AF. Although digoxin is most commonly used, the group is often referred to as *digitalis*, the prototype agent. As potentially lethal side effects can occur, one should have a high index of suspicion for early signs of digoxin toxicity and the lowest effective dose should be used. Periodic monitoring of its efficacy and serum medication and electrolyte levels is wise.

#### Mechanism of Action and Pharmacokinetics

Digitalis increases myocardial contractile force via increased intracellular  $\text{Ca}^{2+}$  concentration, which enhances myofilament cross-bridging. Digitalis also slows cardiac impulse conduction. This is related to changes in cellular ion transport and concentrations that affect the rates and degree of transmembrane potentials.

GI absorption of digoxin varies depending on the preparation; thus, it is important to familiarize oneself with a specific preparation. After oral dosage, peak plasma concentration occurs in 2 to 3 hours and maximum effect in 4 to 6 hours. The half-life is 1 to 2 days, and steady-state plasma concentration

**TABLE 65.24 Beta-Blockers**

<b>[Beta-Blocker Class]</b> <b>Generic (Trade) Name</b>	<b>Oral Dose (mg)</b>	<b>Indications and Unique Properties</b>
<b>[Beta-1 Selective]</b>		
Acebutolol (Sectral)	200 bid–1,200 qd	HTN and ventricular arrhythmia, also angina (off-label); mild intrinsic $\beta$ -mimetic properties
Atenolol (Tenormin)	50 qd–100 qd	IV dosing available for acute MI HTN, angina. Also unapproved for migraine prophylaxis
Betaxolol (Kerlone)	10 qd–20 qd	HTN
Bisoprolol (Zebeta)	5 qd–20 qd	HTN. Also unapproved for migraine prophylaxis
Metoprolol (Lopressor)	50 bid–450 daily	Angina, HTN, compensated CHF; IV dosing available for acute MI
(Toprol XL)	50–100 qd–400 daily	Also unapproved for migraine prophylaxis, HR control in AF, akathisia
<b>(Beta [Nonselective])</b>		
Carteolol (Cartrol)	2.5 qd up to 10 qd	HTN; mild intrinsic $\beta$ -mimetic activity
Carvedilol (Coreg, Coreg CR)	CHF: 3.125 bid–50 bid, if over 85 kg HTN and LV dysfunction: up to 50 total daily dose	Compensated CHF, HTN, and LV dysfunction post-MI; exerts $\alpha$ -1 antagonistic effect Also unapproved for chronic stable angina and idiopathic cardiomyopathy
Labetalol (Trandate, Normodyne)	100 bid–2,400 daily	HTN; $\alpha$ -1 antagonistic properties; IV dosing available for hypertensive emergencies
Nadolol (Corgard)	40 qd–320 daily	HTN and angina; also unapproved for migraine prophylaxis, ventricular arrhythmias, and Parkinsonian tremor
Penbutolol (Levitol)	20 qd–80 daily	HTN; mild intrinsic $\beta$ -mimetic activity
Pindolol (Visken)	5 bid–60 daily	HTN; also angina (off-label); mild intrinsic $\beta$ -mimetic activity
Propranolol (Inderal) (Inderal-LA, Inno-Pran XL)	40 bid–640 daily 80 h to 120 h (ext. rel.)	HTN, angina, cardiac arrhythmias, MI, migraine prophylaxis, and hypertrophic subaortic stenosis (ext. rel.). Also unapproved for generalized anxiety and Parkinsonian tremors (ext. rel.)
Sotalol (Betapace, Betapace AF)	80 bid–640 daily	Ventricular arrhythmias, AF/flutter
Timolol (Blocadren)	10 bid–60 daily	HTN, post-MI, migraine headaches; angina (off-label)

**TABLE 65.25 Calcium Channel Blockers**

<b>Generic (Trade) Name</b>	<b>Typical Oral Dose (mg)</b>	<b>Indications</b>
Amlodipine (Norvasc)	2.5–5 qd–10 qd	HTN, stable and variant angina
Diltiazem (Cardizem)	30 qid–360 qd	HTN (extended preparations), stable and variant angina
(Cardizem CD; Dilacor, Dilacor CR, Tiazac)	60–120 bid–360 qd 180–240 qd–540 qd	Can be use IV for rapid atrial fibrillation
Felodipine (Plendil)	5 qd–10 qd	HTN
Isradipine (DynaCirc, DynaCirc CR)	2.5 bid (or 5 qd of CR)–20 qd	HTN; IV form for HTN emergencies
Nicardipine (Cardene)	20 tid–120 qd	HTN (SR form), stable angina; IV form available for hypertensive emergencies
(Cardene SR)	30 bid–120 qd (SR)	
Nifedipine (Procardia, Adalat)	10 tid–120 qd (IR)	Angina
(Procardia XL, Adalat CC)	30–60 qd–120 qd (ER)	HTN (excessive decline in BP or even stroke may occur if IR form taken SL)
Nimodipine (Nimotop)	60 q4h for 21 d	Only indicated for reduction of cerebral vasospasm following subarachnoid hemorrhage; must start within 96 h of the bleed
Nisoldipine (Sular)	10–40 qd	HTN
Verapamil	80 tid–360 qd	HTN; can also be used IV for treatment of SVT, although adenosine is preferred for this indication
(Isoptin, Calan)	240 qd–480 qd	
(Isoptin SR, Calan SR, Verelan, Covera HS)	Covera HS: 180–480 H/S	

may require 1 week of regular dosage, unless a loading dose is given initially. Increased extracellular potassium ( $K^+$ ) concentrations decrease its tissue binding. Elimination is renal; thus, dose adjustments should be made if there is renal dysfunction.

### **Preparations and dosing**

Maintenance digoxin (Lanoxin, Lanoxicaps, Digitek) doses are generally 0.125 to 0.25 mg qd.

### **Relevant Side Effects and Drug Interactions**

Digitalis toxicity is a frequent occurrence, especially with unmonitored dosing and lack of a high enough index of suspicion for early signs and symptoms of toxicity. These signs often include anorexia, GI disturbances (nausea, vomiting, or diarrhea), fatigue, headache, drowsiness, and visual disturbances. Cardiac abnormalities can also occur, and with increasing toxicity, the risk for severe or even fatal rhythm disturbances increases. In fact, digitalis toxicity can mimic essentially any rhythm disturbance, particularly premature atrial or ventricular beats, paroxysmal atrial tachycardia, ventricular tachycardia, or high degree AV block.

Many drugs may affect the efficacy of digitalis. Certain diuretics and other medications may cause hypokalemia, which increases toxicity risk. Quinidine, verapamil, diltiazem, and amiodarone cause increased plasma digitalis concentrations. Beta adrenergic agonists may increase the risk of cardiac arrhythmias. In addition, drugs that induce hepatic microsomal enzyme activity may increase digitalis metabolism.

### **Diuretics**

#### **Relevance to Psychiatry**

Although diuretics are primarily used for HTN and certain forms of edema, other psychiatric uses have included the acute treatment of immobilization hypercalcemia (e.g., in SCI) (427). Diuretics may also facilitate fluid mobilization in early lymphedema but should not be used for chronic treatment of this condition (428). Diuretic-associated orthostatic hypotension is a potential problem, particularly for transfer and gait training.

#### **Mechanism of Action**

Diuretics in general act by decreasing the volume of extracellular fluid by enhancing urinary excretion through sodium resorption. Because this increases the tubular osmotic gradient, water also is resorbed into the tubules and subsequent diuresis occurs. Each of the three most frequently utilized diuretic classes specifically act in different areas of the tubules to achieve this effect. The thiazides and high-ceiling (or “loop diuretic”) classes are more vigorous in their diuretic, natriuretic, and potassium-wasting effects. Potassium-sparing diuretics are less vigorous in action and because they interfere with the normal sodium-potassium exchange in the distal tubule, potassium tends to be spared from increased secretion into the urine. A less commonly used class is the carbonic anhydrase inhibitors. These alkalinize the urine through increased bicarbonate concentration and, as a result, cause sodium and potassium ions to be excreted. Additional agents with diuretic properties include osmotic agents such as mannitol and methylxanthines (e.g., theophylline).

### **Relevant Side Effects and Drug Interactions**

See Table 65-26.

Potential medication interactions should be considered. These include cardiac toxicity from digitalis due to diuretic-induced hypokalemia, decreased renal lithium clearance, interference with oral hypoglycemics, and increased risk of NSAID-induced renal failure.

### **Nitrates**

#### **Relevance to Psychiatry**

Organic nitrates are commonly used in inpatient rehabilitative settings where there are many patients with coronary artery disease. In addition to their use in angina and in certain patients with CHF, oral or TD nitrates may help to reduce acute BP elevations, such as in autonomic dysreflexia. The psychiatrist should also be well aware of possible deleterious effects in those undergoing intensive rehabilitation. In particular, it is important to prevent orthostatic hypotension and tachycardia through measures such as gradual position changes, especially in the morning, and having patients avoid prolonged standing if lower extremity strength is diminished.

#### **Mechanism of Action and Pharmacokinetics**

After being converted into nitrous oxide within the body, organic nitrates cause smooth muscle relaxation. This occurs by stimulation of intracellular synthesis of cyclic guanosine monophosphate (GMP), which leads to myosin dephosphorylation and loss of smooth muscle contractility.

After oral ingestion, organic nitrates undergo first-pass hepatic inactivation via hydrolysis. Sublingual administration of organic nitrates leads to an onset of action in 1 to 2 minutes and a rapid decrease in effects thereafter. When given orally, higher doses must be used to saturate the hepatic metabolism and prevent their degradation. Subsequently, they have a slow onset of action, with peak effects occurring at 60 to 90 minutes, and a duration lasting from 3 to 6 hours. In contrast, TD application, either by ointment or patch, allows for gradual absorption and prolonged delivery. With the former, the initial effects occur within 60 minutes and last 4 to 8 hours. In dosing by patch, peak effects are achieved after 1 to 2 hours and can last up to 24 hours. It is important to note, however, that long-term continuous use of organic nitrates can lead to the development of tolerance to them. This can be avoided by ensuring a nitrate-free interval for short periods of time (e.g. removing a nitrate patch daily at bedtime and reapplying a new one in the morning).

The efficacy of nitrates in relieving angina pectoris lies in their ability to decrease venous return to the heart (preload) and systemic peripheral resistance (afterload), thereby reducing myocardial oxygen demand. Because they also affect nonvascular smooth muscle, they may relieve atypical chest pain, which can occur in spasmodic conditions of the esophagus or bile ducts.

#### **Dosage and Preparations**

Multiple organic nitrate preparations exist. Sublingual, IV, and inhalant preparations are used in acute anginal episodes, whereas buccal and SR oral tablets, ointments, and patches are preferred for prophylaxis against anginal episodes.

**TABLE 65.26 Commonly Prescribed Diuretics**

[Class] Generic (Trade) Name	Dose (mg)	Other Characteristics and Side Effects
Thiazide		Avoid in patients with allergies to sulfonamide-containing drugs
Chlorthiazide (Diuril)	250–500 PO qd/bid	Available in a suspension form
Chlorthalidone (Hygroton)	25–100 PO qd	Rarely used
Hydrochlorthiazide (Aquazide, E-zide, HCTZ, Esidrix, Microzide, Oretic, Hydrodiuril)	25–200 PO qd	Lower doses effective in antihypertensive combinations; can be used less frequently than daily for maintenance edema management
Indapamide (Lozol)	1.25–5.0 PO qd	An indoline; main use is for HTN
Methylclothiazide (Enduron, Aquatensen)	2.5–10 PO qd	Maintenance dosage for edema may be q.o.d. or 3–5 d/wk
Metolazone (Zaroxilyn)	5–20 PO qd	Used with loop diuretics in edema refractory to loop diuretics alone
Loop		Used for rigorous diuresis and in edema with decreased renal function.
Bumetanide (Bumex)	0.5–2.0 PO qd, 5–1 IV/IM	1 mg equivalent to 40 mg Lasix
Ethacrynic acid (Edecrin)	25–100 PO qd/bid, 5–1 mg/kg IV up to 50	
Furosemide (Lasix)	20–80 PO qd/bid, 1 mg/kg IV up to 20–40	Most commonly used loop diuretic
Torsemide (Demadex)	5–20 PO/IV qd	Equal efficacy with oral or IV doses
Potassium sparing		Possible hyperkalemia, especially if used with ACEIs or ARBs
Amiloride (Midamor)	5–10 PO qd	Rarely used; lack mineralocorticoid side effects
Spironolactone (Aldactone)	25–50 PO qd/bid	Aldosterone antagonist
Triamterene (Dyrenium)	100 PO bid	Rarely used; lack mineralocorticoid side effects

**Relevant Side Effects and Drug Interactions**

The most common side effect is vascular headache that can occasionally be severe. It usually improves, however, with reduction of the dosage and continued use. Postural hypotension may occur but can be relieved by maneuvers that increase central venous return, such as lying supine with leg elevation or with true Trendelenburg positioning. Concomitant use of nitrates with alcohol or antihypertensives can lead to significant hypotension.

**Preparations and Dosing**

See Table 65-27.

**GI MEDICATIONS****Antiemetics****Relevance to Psychiatry**

Nausea is a troublesome symptom that frequently prevents patients from meaningfully participating in a rehabilita-

**TABLE 65.27 Nitrates**

Generic (Trade) Name	Dose
Isosorbide dinitrate	
• Tablets (Isordil, Sorbitrate)	10–40 mg PO at least 6 h apart
• Sublingual tablets (Isordil, Sorbitrate)	1 tab (2.5–10 mg) SL prn
• Sustained release (Isochron, Dilatrate SR)	5–40 mg tid; max of 80 mg PO bid
Isosorbide mononitrate	
• Tablets (ISMO, Monoket)	20 mg PO bid at least 7 h apart
• Extended release (Imdur)	30–240 mg PO qd (start with 30–60 PO qd)
Nitroglycerin	(15 mg/inch)
• Ointment 2% (Nitro-Bid, Nitrol)	0.5 inch q8h, maintenance 1–2 in. q8h; max. 4 in. q4–6h
• Spray (Nitrolingual, Nitro Mist)	1–2 SL sprays prn
• Sublingual (Nitrostat, NitroQuick)	0.4 mg SL prn
• TD (Deponit, Minitran, Nitro-Dur, Nitrodisc, Transderm-Nitro)	1 patch (doses of 0.1 to 0.8 mg/h) 12–14 h daily
Amyl nitrite	1 cap inhaled (2 or more times) for rapid relief of angina

**TABLE 65.28    Antiemetics**

Medication Class and Mechanism of Action	Generic (Trade) Name	Typical Dose (mg)	Other Properties and Side Effects
<i>Phenothiazine derivatives:</i> act at the CTZ and the vomiting center	Prochlorperazine (Compazine)	5–10 PO/IM tid–qid 25 PR q12h IV dosing possible	Antidopaminergic: extrapyramidal reactions and neuroleptic malignant syndrome possible
	Promethazine (Phenergan)	1/kg up to max 25–50 PO/IM/PR q4–6	H-1 receptor blocker, therefore antihistaminergic; much less effect on DA; IV form also available
	Thiethylperazine (Torecan)	10 PO/IM q8	Same as for prochlorperazine
<i>Antihistamines:</i> act at the CTZ and the vomiting center	Dimenhydrinate (Dramamine)	50 PO/IM/IV q4–6	Sedating; TD preparation no longer commercially available
<i>Other:</i> act at the CTZ and vomiting center	Trimethobenzamide (Tigan)	250 PO q6–8 200 IM/PR q6–8	Hypersensitivity and Parkinson-like symptoms have been reported
	Scopolamine (Transderm Scop)	One patch behind ear, change after 3 d prn	Belladonna alkaloid, therefore anticholinergic side effects
Cannabinoids: complex CNS effects, including sympathomimetic	Dronabinol (Marinol)	dosage varies	Chemotherapy-related nausea or anorexia associated with AIDS
Selective serotonin 5-HT <sub>3</sub> receptor inhibitors: blocks receptors in peripheral vagus nerve terminals and CTZ	Dolasetron (Anzemet)	Up to 100 PO single dose (alternate IV dosing)	Prevention of chemotherapy-related or postop nausea
	Granisetron (Kytril)	1 PO bid × 1 d 2 PO single dose (alternate IV dosing)	Prevention of chemotherapy-related or radiation therapy-related nausea
	Ondansetron (Zofran)	8 PO before and 8 h after 8 PO tid (alternate IV dosing)	Prevention of chemotherapy-related, RT-related and postop nausea

tion program. It can be particularly prevalent in patients enrolled in cancer rehabilitation programs who are receiving chemotherapy. Nausea should always evoke suspicion of early digoxin toxicity in patients taking cardiac glycosides. Nausea can be treated with agents from several medication classes, each with their own mechanisms, pharmacokinetic principles, side effects, and drug interactions (Table 65-28).

### Medications that Act by Affecting GI Motility

#### Relevance to Psychiatry

Abnormally slow GI transit can especially occur in diabetic patients. Since psychiatrists commonly manage patients who also have diabetes, knowledge of promotility agents is important. The two most commonly used ones are metaclopramide (Reglan) and cisapride (Propulsid). Use of the latter is limited because of many drug interactions and potentially fatal cardiac dysrhythmias. Metaclopramide is dosed for gastroesophageal reflux and diabetic gastroparesis at 10 to 15 mg orally 30 minutes before meals and sleep, and should be reduced to 5 mg in elderly patients. It can be used for prevention of chemotherapy-induced emesis and is available for IV or IM dosing. Because it is a DA receptor antagonist, CNS side effects and extrapyramidal reactions can occur.

#### Mechanism of Action and Pharmacokinetics

These drugs enhance acetylcholine (ACh) release and/or action at the myenteric plexus, thereby stimulating upper GI peristalsis. This leads to reflux reduction and gastric emptying. Metaclopramide undergoes hepatic conjugation, but otherwise little hepatic metabolism.

### Antidiarrheal Drugs

#### Relevance to Psychiatry

Hospitalized patients commonly complain of diarrhea. This condition obviously can interfere with rehabilitation. Therefore, medications are often used for short-term management of acute, nonspecific diarrhea and may also be used for chronic inflammatory bowel disease–associated diarrhea. They should be avoided, however, when diarrhea is suspected to be the result of obstructive jaundice, fecal impaction, or infection with toxin production. If diarrhea is not controlled within 48 hours, further workup is warranted.

The two most commonly used antidiarrheal agents for hospitalized patients are loperamide (Imodium) and diphenoxylate or its principal metabolite difenoxin, combined with atropine (Lomotil and Motofen, respectively).

#### Mechanism of Action and Pharmacokinetics

As they are opioid derived, antidiarrheal drugs directly inhibit intestinal smooth muscle peristalsis.

**TABLE 65.29 Antidiarrheal Agents**

Agent	Dosage
Kaopectate <sup>a</sup>	2 tabs or 30 mL prn, up to 8 doses in 24 h
Imodium <sup>a</sup>	4 mg initially, then 2 mg s/p loose bowel movement to a maximum of 16 mg/24 h
Lomotil	2 tablets qid or 10 cc qid
Motofen	2 tabs initially, then 1 tab prn to a maximum of 8 tabs/24 h

<sup>a</sup>Also available OTC.**Preparations and Dosing**

See Table 65-29.

**Side Effects and Drug Interactions**

As is expected from medications that impair intestinal motility, abdominal discomfort, and nausea can occur. In addition, opioid-like side effects such as fatigue, drowsiness, or dry mouth can occur. Lomotil and Motofen are chemically related to the narcotic analgesic meperidine (Demerol) and are combined with atropine. They may therefore interact with MAO inhibitors and are likely to cause sedation when

used with other CNS depressants. Lomotil and Motofen may also prolong the biological half-lives of drugs for which the elimination rate is dependent upon microsomal drug metabolizing enzyme systems. Although Imodium is somewhat chemically similar to meperidine, it is not combined with atropine and therefore has a safer side-effect profile and less drug interactions.

**Medications that Reduce Gastric Acid Secretion  
Relevance to Psychiatry**

Besides their use in the prevention and treatment of NSAID-induced GI pathology (see NSAID section of this chapter), these medications are also used for idiopathic gastric and duodenal ulcers, as well as for gastroesophageal reflux disease. They are also often used to prevent stress ulcers and are thus encountered in patients undergoing rehabilitation for stroke, TBI, or SCI. Other than cimetidine that can cause CNS changes in the elderly, they are usually well tolerated and do not interfere with rehabilitation.

**Mechanism of Action and Pharmacokinetics;  
Preparations and Dosing; Relevant Side Effects  
and Drug Interactions**

See Table 65-30.

**TABLE 65.30 Medications that Act by Reducing Gastric Secretion**

Medication Class: Mechanism	Generic (Trade) Name	Usual Oral Dose (mg)	Unique Characteristics and Side Effects
<i>H-2 blockers:</i> Block histamine-2 receptors of gastric acid-producing parietal cells	Cimetidine (Tagamet)	800 h or 400 bid	Because of the change in gastric fluid acidity due to H <sub>2</sub> blockers, GI absorption of various drugs can be altered; IV form also available; replaced by newer agents due to side effects (esp. in elderly and in impaired renal function) and medical interactions
	Famotidine (Pepcid)	40 h or 20 bid	IV form also available
	Nizatidine (Axid)	300 h or 150 bid	
	Ranitidine (Zantac)	300 h or 150 bid	IV form also available
<i>Proton pump inhibitors:</i> decrease gastric acid secretion by inhibiting the parietal cell membrane enzyme that actively transports hydrogen ions out of the cell			Numerous indications, including gastroesophageal reflux disease, gastritis, peptic ulcer disease, erosive esophagitis, and prevention/treatment of NSAID or ASA-induced ulcers. Well tolerated but sometimes nausea, diarrhea, headache, dizziness, and possible gastric bacterial colonization from elevation of gastric fluid pH; inhibition of metabolism of medications processed by cytochrome P-450 system.
	Esomeprazole (Nexium)	20 to 40 qd	
	Lansoprazole (Prevacid)	15 to 30 qd	
	Omeprazole (Prilosec, Zegerid, Rapinex)	20 to 40 qd	
	Pantoprazole (Protonix)	40 qd	
	Rabeprazole (Aciphex)	20 qd	
Prostaglandin analogue: mucosal protection and reduces gastric acid secretion	Misoprostol (Cytotec)	100–200 ug qid (depending on indication)	Diarrhea very common; not to be used in women of child-bearing age due to abortifacant properties from smooth muscle contraction; no known drug interactions

**TABLE 65.31 Laxatives**

Medication Class: Mechanism	Generic (Trade) Name	Common Doses	Unique Characteristics and Side Effects
<i>Bulking agents:</i> contain natural fiber, which increases fecal H <sub>2</sub> O capacity and enhances bacterial floral growth	Psyllium (Metamucil, Fiberall); methylcellulose (Citrucel); polycarbophil (FiberCon, Fiberall)	1 tbsp PO qd–tid; 1 tbsp PO qd–tid; 1 gm PO qid prn	Gritty texture prohibits use in some patients
<i>Colonic stimulants:</i> (“irritant cathartics”) act on colonic and rectal sensory nerve endings upon mucosal contact. Peristalsis, and subsequent purging, then occurs by parasympathetic reflexes	Bisacodyl (Dulcolax); cascara sagrada (Cascara); castor oil (Purge); sodium biphosphate (Fleet enema, Fleet Phospho-soda, Fleet Bisacodyl supp., Fleet Bisacodyl tabs); senna (Senokot) tablets (8.6 mg/tab) or syrup (8.8 mg teaspoon)	5–15 mg PO/PR prn; 325 mg or 5 mL PO qd; 15–30 mL PO qd; 1 PR; 45 mL; 1 PR; 4 tabs; 2–4 tabs PO qd–bid; 10–15 mL PO qd	Dulcolax affects fluid and electrolyte absorption throughout the intestine; Cascara and Senokot act on the large intestine, so there is a delayed effect of approximately 8 h and may cause urine discoloration; Castor oil intestinally hydrolyzed to a cathartic (ricinoleic acid)
<i>Combination products</i>	Docusate/casanthranol (Peri-Colace) senna/docusate (Senokot-S tabs) Milk of Magnesia-Cascara	1–2 caps qd 2, max 4 PO qd 15–30 mL qd	Pericolace capsule, 100 mg docusate /30 mg casanthranol Peri-Colace liquid, 60 mg docusate/30 mg casanthranol per 15 mL
<i>Hyperosmolar agents:</i> (“bulk cathartics”) cause H <sub>2</sub> O secretion into the colon and rectum, leading to loosening and facilitated expulsion of feces.	Magnesium citrate soda; magnesium hydroxide (Milk of Magnesia); Polyethylene glycol (MiraLax, Glycolax) Lactulose (Cephulac, Enulose, Constulose)	200–300 mL PO; 15–60 mL PO 17 grams of powder qd in eight ounces of water 15 to 30 mL (10 to 20 g) up to 60 mL qd	Because of their osmotic concentration, hyperosmolar agents should be avoided in acute CHF and used with caution with impaired renal function, heart disease, and electrolyte imbalances; Fleet products usually used as bowel preps 3 h before a procedure
<i>Miscellaneous agents</i>	Glycerin suppositories; lactulose (Chronulac); mineral oil;	1 PR; 15–30 mL or 10–20 gm powder qd; 15–45 mL PO or 120 mL PR	Glycerin stimulates rectal contraction within 15–30 min via hyperosmotic and irritant actions; lactulose is a synthetic disaccharide converted by colonic bacteria to short-chain organic acids that cause colonic fluid accumulation; mineral oil softens and lubricates stool and is useful for fecal impaction; MiraLax
<i>Stool softeners:</i> surfactant, thus increases stool H <sub>2</sub> O absorption as it descends the lower GI tract	Docusate sodium (Colace) [capsules or syrup/liquid]; docusate calcium (Surfak, Sulfolax)	100 mg PO qd–tid; 240 mg PO qd	May not see the effect until 1–3 d; begin with the highest dose and then reduce when the first bowel movement occurs

## Laxatives

### Relevance to Physiatry

As is true for diarrhea, constipation can also have a significant negative impact upon rehabilitation. Laxatives can facilitate or restore regular bowel movements in constipated patients. Some are used as part of a bowel program in neurologically impaired patients, especially those with SCI (323,324). Many preparations are available (Table 65-31) and their effects range from mild (bulking agents) to more aggressive (hyperosmolar preparations). Caution should be exercised in those with nausea, vomiting, or unexplained abdominal pain.

### Mechanism of Action and Pharmacokinetics; Preparations and Dosing; Relevant Side Effects and Drug Interactions

See Table 65-31.

## HYPNOTICS

### Relevance to Physiatry

Insomnia is frequently associated with major stressors such as injury or illness or conditions such as fibromyalgia, myofascial pain syndromes, and chronic fatigue syndrome (429). It can

**TABLE 65.32 Hypnotic Medications**

Medication Class	Generic (Trade) Name	Usual Oral Dose (mg)	Unique Characteristics and Side Effects
Benzodiazepine	Estazolam (ProSom)	1–2 h, 0.5 (elderly)	Medium half-life of 10–15 h
	Flurazepam (Dalmane)	15–30 h	Long half-life of 70–90 h
	Lorazepam (Ativan)	2–4 h	Medium half-life of 10–20 h
	Temazepam (Restoril)	7.5–30 h	One of the most widely used agent in this class; half-life of 8–25 h
	Triazolam (Halcion)	0.125–0.25 h, max 0.5 qd	Less popular; significant interactions reported with “conazole” antifungals, macrolides, and cimetidine; short $T_{1/2}$ (2–3 h)
Zolpidem (Ambien, Tovalt), an imidazopyridine		Dosage: 5–10 h	
Zaleplon (Sonata), a pyrazolopyrimidine		10 h, 5 in low weight patients	
Eszopiclone (Lunesta), exact mechanism unknown		2 to 3 h, 1 to 2 in elderly	
Ramelteon (Rozerem), a melatonin receptor agonist		8 h	

significantly interfere with rehabilitation due to resultant daytime lethargy, irritability, difficulty with concentration, etc. Hence, treatment of insomnia with hypnotics can play an important role in overall patient management. Hypnotics are commonly used in hospitalized patients in acute care, in rehabilitation units, and rehabilitation hospitals.

### Mechanism of Action and Pharmacokinetics

BNZs exert hypnotic and anxiolytic effects by binding nonselectively to the GABA-benzodiazepine (BZ) receptor complex, particularly in the limbic system, thalamus, and hypothalamus. In doing so, they reduce delta sleep. They are well absorbed, undergo very little first-pass metabolism, are highly metabolized by the liver, are excreted with short elimination half-lives, and their metabolites do not accumulate.

Zolpidem tartrate (Ambien) is structurally unrelated to other hypnotics. It preferentially binds to the omega-1 subunit of the GABA-BZ receptor complex, which is the purported reason for its selective hypnotic effect yet lack of anticonvulsant, anxiolytic, and muscle relaxant properties seen with BNZs. Sleep architecture is relatively preserved in both healthy patients and in those with acute or chronic insomnia. It is rapidly absorbed and has a mean elimination half-life of 2½ hours. It does not accumulate if used for a short term and thus is less likely to cause daytime sedation.

### Preparations and Dosing

See Table 65-32.

### Relevant Side Effects and Drug Interactions

Daytime drowsiness, headache, and fatigue are the most frequently reported side effects in controlled clinical studies involving bedtime BNZ use. Dependence and rebound insomnia can develop, particularly if used regularly for more than a few weeks. These drugs should be used with caution in patients taking other CNS depressants.

Ambien's side-effect profile is superior but still includes daytime drowsiness usually during short-term use and dizziness or

“drugged” feelings with long-term use. As with BNZs, it should be used cautiously in patients taking other CNS depressants.

## HYPOGLYCEMICS

### Relevance to Psychiatry

A psychiatrist often manages patients who have diabetes mellitus as a comorbid medical condition. Proper glucose control is important both acutely, in order to avoid uncontrolled blood sugar elevations or hypoglycemia, and chronically in order to avoid long-term complications (430,431). The effects of exercise on blood glucose levels must be taken into account especially in patients who have not previously exercised regularly.

### Insulin

#### Mechanism of Action and Pharmacokinetics

Insulin is a large polypeptide secreted by pancreatic  $\beta$  cells that lowers blood glucose concentrations by inhibiting hepatic gluconeogenesis and by increasing peripheral glucose uptake and metabolism. It also affects lipid, ketone, and protein metabolism by reducing glycerol and free fatty acid blood concentrations, reducing ketone body formation, and increasing protein synthesis in muscles and other tissues. Insulin's various effects are exerted via interaction with highly specific receptors various target cell membranes. This interaction leads to intracellular mechanisms that produce target cell-specific end organ effects. Exogenous insulin preparations can be of human, porcine, or bovine origin. The latter two differ from human insulin by one and three amino acids, respectively, within the peptide chain.

### Preparations and Dosing

As shown in Table 65-33, insulin preparations can be classified as short acting, intermediate acting, and long acting. Most dosing regimens involve a mixture of short and intermediate-acting insulin preparations given at fixed dosages prior to breakfast and dinner. Another method of dosing insulin is frequent monitoring of blood glucose levels and adjusting

**TABLE 65.33 Insulin Preparations**

Insulin Class	Generic (Trade) Name	Pharmacokinetic Properties		
		Onset	Peak Effect	Duration
Rapid acting	Insulin aspart (Novolog)	15 min	45 min	3–5 h
	Insulin lispro (Humalog)	0–15 min	30–90 min	6–8 h
	Regular; Semilente	30–60 min	2–4 h	8 h
	Insulin glulisine (Apidra)	18–24 min	60 min	4–5 h
Intermediate acting	NPH; Lente	1–2 h	6–12 h	18–24 h
Long acting	Insulin glargine (Lantus) protamine zinc insulin suspension; Ultralente	Slow absorption, with consistent concentration over 24 h		
	Insulin detemir (Levemir)	4–6 h	10–30 h	>36 h
		NA	6–8 h	6–23 h
Amylin analog	Pramlintide (Symlin)			

insulin dosage with each administration accordingly. This is known as *intensive insulin therapy* and has been shown to reduce long-term complications of diabetes.

### Side Effects and Drug Interactions

The most common side effect of hypoglycemic therapy is hypoglycemia, as a result of excessive dose, reduced, delayed, or omitted meals, or factors that reduce insulin requirements, such as exercise. Hypoglycemia is also more common in the elderly and in patients with impaired hepatic or renal function who take longer-acting preparations. The early signs of hypoglycemia may be blunted in patients chronically treated with insulin.

Hypersensitivity may also occur and can range from local skin reactions to more generalized systemic ones, and even injection site subcutaneous fat atrophy. This occurs more commonly with beef and pork insulin preparations; however, it can also occur during treatment with human insulin. Switching the type of preparation and rotation of the injection site may help to reduce these effects.

Many medications can affect blood sugar levels in patients receiving insulin. Those that may cause hypoglycemia include  $\beta$ -adrenergic antagonists, salicylates, and some NSAIDs. In contrast, corticosteroids, oral contraceptives, CaCBs, and some diuretics can blunt the effect of insulin by increasing blood glucose levels.

## Other Parenteral Hypoglycemics

### Pramlintide Ecetate (Symlin)

#### Mechanism of Action and Pharmacokinetics

Pramlintide is an amylin analog. Amylin is a hormone formed in the pancreatic  $\beta$  cells and cosecreted with insulin in response to food intake. In healthy subjects, both these hormones have similar fasting and postprandial patterns. Amylin has several mechanisms that control postprandial glucose, including slowing of gastric emptying, suppressing glucagon secretion, and also acting centrally to reduce appetite. It is used as an adjunct in patients who use mealtime insulin and who have not achieved adequate glucose control despite optimal insulin therapy.

### Preparations and Dosing

It is given prior to major meals. In type I diabetes, it is initiated at 15 mcg subcutaneously and titrated to a maintenance dose of 30 or 60 mcg as tolerated. In type II diabetes, the starting dose is 60 mcg and increased to a dose of 120 mcg as tolerated. When initiating therapy with pramlintide, it is crucial to decrease insulin dosing initially to reduce the risk of insulin-induced hypoglycemia.

### Side Effects and Drug Interactions

Although pramlintide alone does not cause hypoglycemia, it increases the risk of insulin-induced severe hypoglycemia, particularly in patients with type I diabetes.

## Exenatide (Byetta)

### Mechanism of Action and Pharmacokinetics

Sharing a similar amino acid sequence with glucagon-like peptide-1 (GLP-1), exenatide binds to the GLP-1 receptor, leading to an increase in both synthesis and secretion of insulin from pancreatic  $\beta$  cells in the presence of elevated blood glucose concentrations. It also lowers serum glucagon levels in the presence of hyperglycemia, slows gastric emptying, and reduces food intake. It is used as adjunctive therapy to improve glycemic control in patients with type II diabetes mellitus who are taking either or a combination of metformin, a sulfonylurea, or a thiazolidinedione but have not achieved adequate glycemic control.

### Preparations and Dosing

Initially 5 mcg subcutaneously before breakfast and dinner. Can be increased to 10 mcg twice daily.

### Side Effects and Drug Interactions

Exenatide, in combination with oral hypoglycemic medications, particularly a sulfonylurea, may have an increased risk of hypoglycemia. Its use is commonly associated with GI adverse reactions, including nausea, vomiting, and diarrhea. It is not recommended for use in patients with severe renal impairment. It can reduce the efficacy of acetaminophen, digoxin,

lovastatin, and certain oral antibiotics. It can lead to an increase in INRs in patients taking warfarin.

### Oral Hypoglycemics

#### *Mechanism of Action and Pharmacokinetics*

Although the exact mechanisms of action vary somewhat according to the chemical class as shown in Table 65-34,

all depend upon a certain degree of endogenous insulin production; thus, they are not effective in treating type I diabetes. All are well absorbed from the GI tract.

#### *Preparations and Dosing; Relevant Side Effects and Drug Interactions*

See Table 65-34.

**TABLE 65.34 Oral Hypoglycemic Agents**

Class: Mechanism of Action	Generic (Trade) Name	Usual Oral Dose (mg) (Starting Dose/Maximum)	Unique Characteristics and Side Effects
Sulfonylureas (first generation): stimulate insulin release from pancreatic $\beta$ cells and increase the insulin sensitivity of various peripheral tissues	Chlorpropamide (Diabenese); tolbutamide (Oramide, Orinase); tolazamide (Tolamide, Tolinase)	100–250/1,000 qd; 250–500/3,000 qd (daily or divided into two doses); 100–250/1,000	Chlorpropamide has a very long duration -up to 24 h, making it relatively dangerous, esp. in the elderly; tolbutamide has a duration up to 10 h
Sulfonylureas (second generation) Same mechanism as earlier	Glimepiride (Amaryl); glipizide (Glucotrol, Glucotrol XL); glyburide (DiaBeta, Micronase, Glynase)	1–2/8 qd; 5/40 qd (divided into two daily doses if >15/d is required, max dose of XL 20 qd); 2.5–5/20 qd	Starting doses of glipizide and glyburide 2.5 and 1.25, respectively, recommended in elderly; duration up to 10 h
Biguanides: improve glucose tolerance in patients with NIDDM without inducing hypoglycemia; lowers both basal and postprandial glucose levels by decreasing hepatic glucose production, decreasing intestinal glucose absorption, and improving insulin sensitivity	Metformin (Glucophage, Glucovance, Glucophage XL)	500 qd or bid/2,550 qd (higher doses usually divided into bid or tid)	May cause potentially serious lactic acidosis in those with abnormal renal or hepatic function; thus, it is contraindicated in these patients and should be temporarily held in patients undergoing radiologic studies involving injectable contrast agents and in those who are dehydrated
Glucosidase inhibitors: decrease the digestion of ingested carbohydrates, thereby reducing postprandial hyperglycemia; possess no systemic effects	Miglitol (Glyset); acarbose (Precose)	Both started at 25 tid; individualized dosing to max of 100 tid	Metabolized in the GI tract; contraindicated in patients with inflammatory bowel disease or intestinal obstruction
Meglitinide: stimulates insulin release	Repaglinide (Prandin)	0.5–2 tid/max of 16 qd in divided doses (tid)	Most common adverse effect is hypoglycemia
Other agent, amino acid derivative having similar action to meglitinide	Nateglinide (Starlix)	120 tid	Most common adverse effect is hypoglycemia; to be used with caution in presence of liver dysfunction
Thiazolidinediones: decrease insulin resistance in peripheral tissues by stimulating the peroxisome proliferator-activated receptor	Pioglitazone (Actos); rosiglitazone (Avandia)	15–30/45 qd; 4/8 qd	May cause fluid retention, thus to be used cautiously in patients with CHF or edema; liver function should be monitored
Dipeptidyl peptidase-4 inhibitor: believed to act on the slowing the inactivation of incretin hormones such as glucagon-like peptide-1 and glucose-dependent insulinotropic polypeptide	Sitagliptin (Januvia)	100 qd	Used in type II diabetes alone or as in combination with metformin or a peroxisome proliferator-activated-receptor agonist. Dosage reduction is necessary in moderate to severe renal impairment

## RESPIRATORY MEDICATIONS

### Decongestants, Expectorants, and Mucolytics Relevance to Psychiatry

Respiratory tract disorders and infections are commonly encountered in rehabilitation patients. Various medications are used in managing these conditions (Table 65-35). Decongestants treat upper respiratory congestion and the increased mucosal secretion that occurs in colds, seasonal allergies, or infections. Particularly when combined with postural drainage and percussion, expectorants and mucolytics are useful in facilitating pulmonary toilet through improving the quality and expulsion of mucus. Selective  $\beta$ -2-adrenergic agonists are useful in the treatment of reversible airway obstruction in bronchial asthma or COPD. Their use in exercise-induced asthma also has direct psychiatric applications. Anticholinergic medications can be of benefit in relieving bronchoconstriction, particularly in COPD. Finally, inhaled glucocorticoids and leukotriene inhibitors, a newer medication class, are effective in maintenance therapy of asthma.

## TBI MEDICATIONS

Each year more than 1.5 million Americans survive a TBI, among which 80,000 to 90,000 are left with permanent disability each year. An estimated 5.3 million people in the United States live with long-term disability from TBI (432). Currently, there are no medications that are FDA approved to treat the early or late sequelae of TBI. The complex nature of the injury and recovery, along with previous research failures, has created pharmaceutical industry apathy. Medications used to treat the behavioral and cognitive consequences of TBI are often based on success in other disorders with similar symptoms. Most TBI population neuropharmacology studies are just case reports.

The TBI manifestations for which medications are most commonly used include disorders of memory, arousal, attention, concentration, initiation, mood, and behavior. Before drug therapy is started, a careful review of the patient's current medications is warranted since medications commonly used for other medical conditions may cause or exacerbate the TBI manifestation (Table 65-36). In general, non-centrally acting medications should be used since these are less likely to have cognitive side effects. Only after eliminating medications with these unwanted side effects and potential medication interactions should initiation of new drugs be considered.

Cognitive and behavioral impairment in the patient with TBI results from neurochemical alterations. These alterations are caused by shear injury of the ascending and descending cortical pathways to the brainstem, along with hypoxic lesions, contusions, and hemorrhages (433). More specific understanding of the pathophysiology of TBI on a cellular and neurochemical level will allow clinicians to tailor the pharmacologic treatment to individual patients. The following will describe those agents more commonly utilized in the patient with TBI categorized by predominant neurochemical activity.

### Agents that Act on Serotonin

In addition to their use in neuropathic pain and depression discussed elsewhere in this text, SSRIs are also used in the setting of TBI to treat sleep disturbance, agitation, affective disorders, emotional incontinence, aggression, and impaired arousal (434,435). SSRIs are preferred to TCAs in the TBI population since they have fewer cognitive side effects. The use of SSRIs in TBI is directly related to serotonin's multiple roles in brain functioning including sleep initiation, sexual response, movement, mood, aggression, anxiety, appetite, and addictive behaviors (436).

### Trazodone

Trazodone is specifically used in TBI patients for agitation (dosed 25 to 100 mg q6h around the clock or prn) and for sleep disturbance (initiated at 25 mg H/S and titrated up to 300 mg to achieve 6 to 8 hours of sleep) (437). Its role in sleep disorders is particularly important as insomnia occurs in more than 50% of TBI patients both early and late after injury and may exacerbate disability by further impairing arousal, attention and increasing one's susceptibility to confusion and agitation (438).

### SSRIs

These SSRIs are commonly used for other cognitive/behavioral manifestations besides sleep disturbance. Sertraline shows the best evidence for depression treatment effectiveness and tolerability among the SSRIs. Dosages are the same as recommended for depression. Slow titration and clinical monitoring is necessary to avoid apathy, an SSRI side effect (436).

### Agents that act on Catecholamines

Cerebral catecholamines are produced in the sympathetic ganglia from the amino acid tyrosine. DA is enzymatically converted to NE and then to epinephrine. An increase in any one of the catecholamines increases the others. DA cell bodies are primarily in the substantia nigra and hypothalamus. There are five types of DA receptors, each with specialization of action. DA neuronal connections have important effects on attention, arousal, and memory (439). NE CNS cell bodies are found in the locus ceruleus. Although this small nucleus contains only several hundred neurons, it sends axons to all CNS regions. Catecholamines are thought to play an important, although not fully defined, role in recovery after brain TBI. Catecholamine antagonists should therefore be minimized to avoid the risk of detrimental effects on functional outcomes. A detrimental effect from haloperidol and a beneficial effect of dextroamphetamine on motor recovery were reported in an animal model (440). Significantly poorer motor and functional outcomes in CVA patients exposed to catecholamine antagonists were then reported (441). Finally, a longer duration of posttraumatic amnesia in those treated with haloperidol for posttraumatic agitation was found in a retrospective review of rehabilitation outcomes in severe TBI (442).

In contrast, catecholamine agonists have a beneficial effect on motor control and executive function, with a

**TABLE 65.35 Respiratory Medications**

Medication Class (Mechanism)	Generic (Trade) Names	Dose	Unique Characteristics and Side Effects
<i>Anticholinergics</i> : relieve bronchoconstriction via antagonism of muscarinic cholinergic receptors	Ipratropium bromide (Atrovent) Tiotropium (Spiriva)	2 puffs (by metered-dose inhaler) qid, up to 12 puffs for every 24 h; maximal clinical effects in 30–90 min and last for 4 h 18 mcg inhaled qd	Most cause significant systemic side effects because of easy absorption; fewer side effects with ipratropium and tiotropium because very little respiratory or GI absorption.
<i>Decongestants</i> ( $\alpha$ -1 adrenergic agonists): nasal mucosa blood vessel vasoconstriction, thus decreased secretion and congestion	Ephedrine, epinephrine, naphazoline, oxymetazoline, phenylephrine, phenylpropanolamine, pseudoephedrine (Sudafed), tetrahydrozoline, and xylometazoline	Depends upon the particular preparation	Decreases secretions and congestion, also used in combination with agents such as expectorants, antitussives, or antihistamines; side effects, H/A, dizziness, increased BP, and palpitations
<i>Expectorants</i> : not clearly understood how they enhance respiratory tract secretion production, but make it easier to advance sputum upward	Guaifenesin (Robitussin, Humibid LA, Guaiatuss, Fenesin, Guaifenex LA, Organidin), terpin hydrate	100–400 mg PO q4h or 600–1,200 mg PO q12h (extended release)	Usually given orally, either alone or in combination with other respiratory agents; GI distress, especially in high doses; in extended usage, those containing iodide may cause iodism, hypothyroidism or hypersensitivity
<i>Mucolytics</i> : decrease mucus viscosity by splitting mucoprotein disulfide bonds	Acetylcysteine (Mucomyst, Mucosol)	6–10 cc 10% or 3–5 cc 20% solution; nebulized form q6–8h	Possible nausea and vomiting, stomatitis, or rhinorrhea
Inhaled steroids: inhibit inflammatory cells and mediators		Adverse effects are similar to those that occur with systemic glucocorticoids; adrenal suppression is not as common as with systemic use, except for the more potent inhaled forms or if used at higher than recommended dosages; oral candidiasis may occur; caution needs to be exercised when changing to inhaled steroids from systemic dosage; not intended to alleviate acute asthma	
	Beclomethasone (Beclovent, Vanceril); Budesonide (Pulmicort); Flunisolide (AeroBid); Fluticasone (Flovent); Triamcinolone (Azmacort) Mometasone (Asmanex Twisthaler)	2 puffs (84 mcg) tid–qid, max 20 puffs/24 h; 200 mcg/puff, 1–2 puffs bid, max 4 puffs bid; 250 mcg/puff, 2 puffs bid, max 4 puffs bid; 2–4 puffs bid, max of 880 mcg bid; 2 puffs (200 mcg) tid–qid or 4 puffs bid, max 16 puffs/24 h 1–2 puffs HS or 1 puff bid, 2 puffs bid if prior oral corticosteroids used	Flunisolide is the most potent of these inhaled drugs; fluticasone inhaler available in strengths of 44, 110, 220 mcg
Leukotriene inhibitors: block leukotriene receptors found in the lung airways (montelukast and zafirlukast) or inhibit the formation of certain leukotrienes (LTB <sub>4</sub> , LTC <sub>4</sub> , LTD <sub>4</sub> , LTE <sub>4</sub> ) by specifically inhibiting 5-lipoxygenase (zileuton)	Montelukast (Singulair); zafirlukast (Accolate); zileuton (Zyflo)	10 mg qPM; 20 bid; 600 qid	Common side effects are headache, abdominal discomfort, and cough; also, zafirlukast and zileuton may elevate protimes in patients on warfarin; also, zileuton may augment the effects of propranolol and may cause elevated liver enzymes
<i>Selective <math>\beta</math>-2-adrenergic agonists</i> : affinity for $\beta$ -2 adrenergic receptors in bronchiolar smooth muscles	Albuterol (Proventil, Ventolin, Volmax), Arformoterol (Brovana), bitolterol (Tornalate), formoterol (Foradil), isoetharine (Bronkosol, nebulized; Brokometer, inhaled), levalbuterol (Xopenex), metaproterenol (Alupent, Metaprel, ProMeta), pirbuterol (Maxair), salmeterol (Serevent), terbutaline (Brethine, Bricanyl)	Response rate varies with administration mode: rapid response to aerosol inhalation or subcutaneous injection; delayed but longer if given orally	Tachycardia, arrhythmias, and myocardial ischemia, especially with underlying cardiac disease

**TABLE 65.36 Medications that Can Impair Cognition**

Aminophylline, anticholinergic agents (e.g., Benadryl), anticonvulsants, antiemetics, antipsychotics, barbiturates,  $\beta$ -blockers, BNZs, central-acting antihypertensive agents (e.g., Clonidine), gastric motility agents (e.g., metoclopramide), cardiac glycosides,  $H_2$  blockers, hypnotics, opiates

resultant improvement in arousal, attention, processing speed, and depression (439). A beneficial effect of a single dose of amphetamine in the motor function of CVA patients was demonstrated (441). Catecholamine agonist side effects include hallucinations, GI upset, orthostasis, and dyskinesias.

### Carbidopa/Levodopa

This presynaptic DA agonist is used in Parkinson's disease and is reported to improve cognition in TBI patients with persistent deficits and to increase arousal after TBI and encephalitis (443–445). It is used at 25/100 mg tid up to 25/250 mg 8x/ day.

### Bromocriptine (Parlodel)

This DA agonist has been reported in case studies to enhance functional recovery in vegetative TBI patients (446). It is initiated at 2.5 mg q AM with slow titration up to 60 mg qd in divided doses with careful monitoring for nausea.

### Amantadine (Symmetrel)

Amantadine facilitates DA action at presynaptic and postsynaptic receptors and is thought to have neuroprotective properties by acting as an NMDA receptor antagonist (447). It has been reported to improve arousal, attention, concentration, and decrease agitation but can lower the seizure threshold (447,448). Studies have recently suggested that amantadine may hasten recovery from diffuse axonal injury and improve recovery after severe TBI (449,450). Dosing is 100 to 400 mg divided qd to bid.

### Methylphenidate (Ritalin)

Ritalin blocks presynaptic DA and NE reuptake. It is most commonly used for impaired initiation, speed of processing, concentration, and attention. More recent studies of Ritalin show positive effects on attention and speed of processing (451). It has been inferred from studies that methylphenidate's action early after TBI is related to its effect on attention and concentration leading to increased therapy participation and thus faster functional recovery (452–454). To avoid insomnia, it should be given early in the day at 5 to 60 mg in divided doses. Although anorexia, arrhythmias, and HTN are potential side effects, studies have not supported that it increases seizure risk or has a significant effects on HR or BP (455,456).

### Atomoxetine (Strattera)

Atomoxetine is a selective NE reuptake inhibitor currently indicated for attention-deficit hyperactivity disorder in children

and adults. This agent increased noradrenergic activity in the locus ceruleus and prefrontal cortex. In the TBI population, this novel stimulant may be useful for attention, hypoarousal, fatigue, and as an adjunct for depression. This agent is well tolerated and thought to have lower abuse potential than traditional stimulants. Dosage ranges from 25 mg in the morning to 100 mg. Dosages greater than 40 mg are generally divided to bid early in the day. No published studies to date have been done in the TBI population, but trials on fatigue and cognitive impairment are warranted (457).

### Agents that Affect Ach

Ach is primarily produced in the nucleus basalis of Meynert and is the neurotransmitter most involved with memory (458). Cholinergic fiber loss is thought to play a key role in attention and memory deficits in Alzheimer's disease and TBI (459). The Ach system has therefore been targeted for pharmacologic modulation to enhance memory. Older cholinergic agents, such as physostigmine and tacrine, had limited use due to systemic side effects and short half-lives. More recently, a new class of acetylcholinesterase inhibitors has been FDA approved for dementia and has been studied in TBI. Smaller studies have behavioral and memory improvement in subjects taking donepezil (Aricept) (458) without significant side effects. More recently, a multicenter placebo-controlled trial of rivatigmine (Exelon) to treat cognitive deficits showed promising results for patients with moderate to severe cognitive deficits (459).

Agitation is a common occurrence in the TBI recovery period (435). Before considering an agent to treat this, any medication that may potentiate agitation by impairing cognition should be minimized (see Table 65-36), environmental modifications should be instituted to minimize unnecessary stimuli and assist with orientation and disordered sleep-wake cycles should be treated as needed. Pharmacologic treatment for agitation spans a broad range of medications including: anticonvulsants, antidepressants, antihypertensives, antipsychotics, BNZs, buspirone, stimulants, and amantadine (435). Treatment choice is based on type and frequency of target behaviors. Optimally, the medication should minimize agitation without impairing arousal and cognition. When possible, one should be chosen that also treats a coexisting condition. Careful monitoring of target behaviors and side effects is critical for successful treatment.

### Miscellaneous Agents: Modafinil

Hypoarousal and fatigue are common complaints after TBI and can lead to poor cognitive and physical functioning. Stimulants can be effective in some patients. Modafinil (Provigil) is approved to treat narcolepsy. Modafinil was reported to reduce fatigue in multiple sclerosis and was well tolerated at 200 mg qd (460). For the TBI patient, dosing should start at 100 mg and then can be titrated up to 400 mg. No published studies to date have been done in the TBI population, but trials on fatigue are currently being done. Although Modafinil's mechanism of action is still illusive it works in the hypothalamus to promote wakefulness.

# The Pharmacology of Analgesic Agents

*Analgesia* is the relief of pain and is achieved by removing the painful stimulus, blocking the generation of nerve impulses at sensory nerve endings, or reducing signal strength in pain pathways. Analgesia is achieved through the systemic administration of either narcotic or nonnarcotic analgesic agents. *Anesthesia* is the loss of all sensation with or without the loss of consciousness and can be achieved by blocking the generation of nerve impulses at sensory nerve endings or reducing signal strength in pain pathways. Anesthesia is achieved by either local application or systemic administration of anesthetic agents. Each of these groups of agents has as a therapeutic goal to reduce *pain perception*, which is the process whereby the brain integrates both sensory and emotional components of nociceptive or neuropathic input.

The process of nociception involves activation of specialized sensory receptors (nociceptors) in nerve endings by noxious insults such as inflammation or injury. A diverse array of chemical mediators, including prostaglandins, leukotrienes, bradykinin, adenosine triphosphate (ATP), histamine, acetylcholine, substance P, and serotonin, either directly or indirectly lower the threshold for activation of nociceptors on primary afferent neurons that terminate in the dorsal horn of the spinal cord. Synapses are formed with spinal neurons that project to supraspinal structures involved in processing and integrating nociceptive inputs resulting in the perception of pain.

A number of different neurotransmitters and neuropeptides, as well as ion channels, have been implicated in playing both direct and indirect roles in modulating signal strength in spinal and supraspinal nociceptive relay circuits (1,2). For example, glutamate released from primary sensory terminals activates both *N*-methyl D-aspartate (NMDA) and non-NMDA subtypes of receptors; substance P and calcitonin gene-related peptide (CGRP) are colocalized and presumably co-released from terminals of primary afferents; adenosine and protein kinase C appear to play a role in nociceptive signaling; endogenous opioid peptides modulate both ascending (pain perception) and descending (pain control) signaling in nociceptive relay circuits; norepinephrine and serotonin mediate one component of descending control of nociceptive relay circuits; glutamate is also responsible for excitatory conduction in brain pathways mediating nociception and awareness; gamma-aminobutyric acid (GABA) decreases neuronal signal strength by increasing inhibitory conduction in nociceptive pathways; and ion channels ( $\text{Ca}^{2+}$ ,  $\text{Na}^{+}$ ,  $\text{K}^{+}$ ) mediate axonal as well as synaptic conduction in nociceptive pathways resulting

in both excitatory and inhibitory transmission. Given the complexity of nociceptive signaling circuits, antidepressants, anticonvulsants, neuroleptics, corticosteroids, NMDA receptor antagonists, central nervous system (CNS) stimulants, and  $\alpha_2$  receptor agonists are employed in the management of pain syndromes with varying results. Frequently, these agents are used in combination, especially with the nonnarcotic and narcotic analgesics.

Based on the actions of these various mediators, analgesic agents either block or augment signaling, resulting in a decrease in pain perception. Of the large group of agents noted above, this chapter focuses on nonnarcotic and narcotic analgesic agents, which have as their primary clinical use the management of moderate and severe pain, respectively. Typically, these agents are the first line of treatment for pain syndromes and as such provide a backbone for combination therapy with secondary agents. As such, this chapter is intended to provide an overview of these two groups, rather than a detailed account of individual agents. Dosages and summary of usage are found in Chapters 83 and 65.

## NONNARCOTIC ANALGESIC AGENTS

Nonnarcotic analgesics (aspirin, acetaminophen, propionic acid derivatives, and cyclooxygenase II [COX II] inhibitors) provide relief of low- to moderate-intensity pain such as headache, myalgia, arthralgia, and other pains arising from integumental structures. Antipyresis (fever reduction) is also a prominent action of the nonnarcotic analgesics. In contrast to acetaminophen, the salicylates, propionic acid derivatives, and selective COX II inhibitors all exhibit significant anti-inflammatory effects. In general, this group of agents is available over the counter and thus widely available for self-medication and also abuse (3). Consumption is driven by public who have become increasingly aware of managing their own health status as well as aggressive marketing campaigns by manufacturers of these products. As a result adverse reactions and interactions are occurring with increasing frequency, especially in the elderly population.

### Salicylates and Propionic Acid Derivatives (Ibuprofen, Naproxen, Ketoprofen)

Acetylsalicylic acid (ASA), also known as aspirin, is absorbed rapidly following oral administration, partly from the stomach

but mostly from the upper small intestine. Appreciable concentrations are found in plasma in less than 30 minutes, with peak blood levels occurring within 1 to 2 hours. The rate and extent of absorption are determined by a number of factors, including the disintegration and dissolution rates of tablets, the pH at the mucosal surface (acid conditions favor salicylate absorption due to increasing the nonionized or uncharged fraction), and gastric emptying time.

Aspirin is rapidly hydrolyzed by tissue and blood esterases to acetic acid and salicylic acid (salicylate), with the salicylate being distributed throughout most body tissues. Eighty to ninety percent of the salicylate is bound to plasma proteins, especially albumin. In the liver, salicylate is either conjugated with glycine to form salicyluric acid, conjugated with glucuronic acid to form ester or ether glucuronides, or metabolized (1%) to gentisic acid. The plasma half-life of aspirin is 15 minutes and that of salicylate 2 to 3 hours in low doses and 15 to 30 hours at high or toxic doses (4). This dose-dependent elimination is a result of the limited availability of hepatic glycine to form salicyluric acid and the availability of glucuronic acid to form glucuronides. As a result, at these high concentrations, there is increased unchanged (free) salicylate in the urine. Renal excretion of free salicylate is highly variable and is pH dependent; as little as 5% free salicylate is excreted in acid urine, and up to 85% free salicylate is excreted in alkaline urine (5).

After oral administration, the propionic acid derivatives (the “profens,” e.g., ibuprofen, naproxen, ketoprofen) are rapidly absorbed; peak concentrations vary from 1 to 2 hours (half-life, 2 hours) for ibuprofen, 2 to 4 hours (half-life, 14 hours) for naproxen, and 1 to 2 hours (half-life, 2 hours) for ketoprofen. The propionic acid derivatives are extensively bound (99%) to plasma proteins, usually albumin. The concentration of the propionic acid derivatives may be higher in synovial fluid than in plasma. These agents are extensively metabolized in liver, with more than 90% of an ingested dose of the propionic acid derivatives excreted in the urine as water-soluble metabolites or their conjugates.

The analgesic and anti-inflammatory actions of both the salicylates and propionic acid derivatives are a direct result of their ability to inhibit prostaglandin synthesis. Intermediates in prostaglandin biosynthesis or prostaglandins themselves sensitize pain receptors to mediators such as kinins, histamine, 5-hydroxytryptamine (5-HT), and so forth, which are released as a result of tissue damage. Salicylates and the propionic acid derivatives decrease prostaglandin synthesis through inhibition of prostaglandin synthase I and II (COX I and II) at both central and peripheral sites (6). COX I is *constitutive* and expressed in most tissues, including those involved with kidney function and gastric cytoprotection. COX II is *inducible* and activated by cellular mediators released owing to tissue damage and in part is responsible for the inflammatory response. Although both COX I and COX II isoenzymes are inhibited by these agents, there is considerable variation in potency; naproxen is about 20 times more potent than aspirin or ibuprofen. In addition to inhibiting prostaglandin

synthesis, both aspirin and the propionic acid derivatives inhibit the migration of polymorphonuclear leukocytes and macrophages into inflammation sites and stabilize lysosomal membranes (thus decreasing the release of mediators from granulocytes, basophils, and mast cells), furthering the anti-inflammatory properties of these agents. Aspirin and the propionic acid derivatives effectively penetrate joint fluid to maintain an anti-inflammatory action that exceeds the plasma half-life (7).

Inhibition of prostaglandin synthesis also mediates the antipyretic actions of aspirin and the propionic acid derivatives (8). Bacterial pyrogens stimulate the production of interleukin-1 (IL-1) in macrophages, which in turn stimulates prostaglandin synthesis through activation of COX in or near the hypothalamus (9). The increase in prostaglandin E-2 (PGE<sub>2</sub>) elevates body temperature by interfering with hypothalamic temperature control mechanisms, which regulate heat production versus loss. By blocking prostaglandin synthesis, aspirin and the propionic acid derivatives facilitate heat loss and reduce elevated body temperature.

The antiplatelet effects of aspirin have received significant notoriety with regard to reducing heart attacks and stroke. Aspirin as ASA before deacetylation in the portal circulation irreversibly acetylates COX in platelets (presystemic inhibition), thus blocking the synthesis of thromboxane A<sub>2</sub> and hence the role in platelet aggregation (10). Platelets are particularly sensitive to ASA's effects because they do not synthesize new COX; the effects of a single dose can last 8 to 10 days (11). The propionic acid derivatives and salicylic acid do not irreversibly inhibit the COX, and thus, it has not been established if these agents produce similar benefits.

The widespread use of aspirin and the propionic acid derivatives provides significant documentation for the adverse side effects of these agents. The most prominent side effect is gastric irritation, and up to 40% of patients taking aspirin have been demonstrated to experience this problem (12). The propionic acid derivatives have significantly less gastric irritation, but this varies from one agent to another and one patient to another. Prostaglandins protect the gastric mucosa by reducing gastric acid production and release. Inhibition of COX I by these agents releases the prostaglandin inhibitory effect on gastric acid production leading to gastric irritation and potential gastric and duodenal ulcers. Coadministration of a prostaglandin analog (misoprostol) can reduce these side effects (13).

Prostaglandins also influence salt and water excretion by regulating renal blood flow and by direct effects on the renal tubules. Because both COX I and COX II are expressed in the kidney, enzyme inhibition can lead to side effects such as fluid retention and electrolyte imbalance (14). Patients with renal disease appear to be most sensitive to the salicylates and propionic acid derivatives such that a reversible decrease in GFR, interstitial nephritis, and nephrotic syndrome may occur. The potential for renal side effects is greater with agents that have a longer half-life, including agents that have greater selectivity for the COX II isoenzyme.

Children with chicken pox or flulike symptoms who take aspirin are up to 25 times more likely to acquire Reye's syndrome (15). Reye's syndrome is a deadly disease of children and teenagers occurring in the aftermath of a viral infection (especially the influenza virus) (16). Aspirin administration, in conjunction with viral illnesses, appears to damage hepatic mitochondrial membranes in genetically predisposed individuals, leading to liver injury and encephalopathy. A warning now appears on products containing aspirin in order to avoid the possible complications associated with Reye's syndrome.

Hypersensitivity reactions to aspirin include asthma (8% to 20% of adult asthmatics) (17), skin rashes, angioedema, and potentially anaphylactoid reactions. Patients with asthma and nasal polyps may experience further sensitivity to aspirin, including bronchospasm and hypotension (18). An additional consideration with both acute and chronic use of aspirin is the prolongation of bleeding time. Although alterations in bleeding time have not been reported to occur with the propionic acid derivatives, hypersensitivity reactions have been reported (19).

Toxicity to aspirin has been well documented, largely because of the general availability of aspirin in household medicine cabinets. Mild aspirin toxicity or salicylism includes headache, dizziness, mental confusion, tinnitus, nausea, and vomiting. These symptoms are *dose dependent* and resolve with reducing the dosage (20). Severe aspirin toxicity is marked by hyperventilation due to increased CO<sub>2</sub> production from salicylate-induced uncoupling of oxidative metabolism in skeletal muscle and direct stimulation of the medullary respiratory center. Respiratory alkalosis, which is compensated for by increased sodium and potassium bicarbonate excretion, leads to severe disturbances in acid-base balance proceeding to convulsions, coma, and, after a period of unconsciousness, death from respiratory failure. Treatment is symptomatic in mild cases of poisoning, but administration of intravenous fluids and correction of acid-base and electrolyte balance is required in more severe cases. Alkalinization of the urine will increase the excretion of free salicylate (21).

Because of their widespread use, drug interactions are not unusual with administration of aspirin and the propionic acid derivatives (22,23). In particular, any other agent that produces gastric irritation potentiates the effects of these drugs on the gastric mucosa. Oral anticoagulants are displaced from plasma protein-binding sites by these agents, which results in an increase in anticoagulant action. Among a number of drugs, combined administration with aspirin can lead to an increase in free versus bound tolbutamide, chlorpropamide, and phenytoin as a result of displacement from plasma protein-binding sites.

### COX II Inhibitors

The selective COX II inhibitors have garnered much press lately based on the withdrawal of rofecoxib (Vioxx) from clinical use and the precautions for using celecoxib (Celebrex) (24). Along with valdecoxib (Bextra) and newer compounds such as etoricoxib, these compounds are second-generation

nonsteroidal anti-inflammatory agents that demonstrate selectivity for the COX II enzyme (25). Based on selectivity for the COX II enzyme, the therapeutic advantage of these agents is a reduction in gastrointestinal side effects while producing anti-inflammatory effects comparable to the propionic acid derivatives (26,27). The use of the COX II inhibitors is indicated primarily in clinical settings where gastrointestinal side effects preclude the use of aspirin or the propionic acid derivatives (28). However, although the gastrointestinal side effect profile is reduced, contraindications such as allergy, aspirin-induced asthma, and compromised renal function still should be considered. Of greater concern is the risk of cardiovascular and cerebrovascular events with COX II inhibitors which have resulted in the worldwide withdrawal of rofecoxib and significant restrictive labeling for other agents in this class. Such warnings provide even greater concern for potential reactions and interactions when combined with over-the-counter agents such as the propionic acid derivatives administered for long periods of time (29).

### Acetaminophen

Acetaminophen has *analgesic* and *antipyretic* actions, which are comparable to therapeutic doses of aspirin and the propionic acid derivatives. The mechanism whereby acetaminophen produces these actions is unclear because it demonstrates weak inhibition of COX I and COX II and also does not suppress inflammation. Studies suggest that the weak inhibition of COX and hence lack of anti-inflammatory action may be due to the presence of high concentrations of peroxides found at inflammatory sites which inactivate the acetaminophen molecule (30). The presence of a COX III isoenzyme that acetaminophen selectively inhibits or the production of reactive metabolites by the peroxidase function of COX II may further explain the lack of anti-inflammatory actions of acetaminophen (31,32).

Acetaminophen is rapidly and almost completely absorbed from the gastrointestinal tract. The concentration in plasma reaches a peak in 30 to 60 minutes, with a half-life in plasma of 2 to 3 hours. Unlike aspirin and the propionic acid derivatives, acetaminophen is relatively uniformly distributed throughout most body fluids; binding of the drug to plasma proteins is 20% to 50% (33). Practically, no acetaminophen is excreted unchanged, and the bulk is excreted after hepatic conjugation with glucuronate (about 60%) or sulfate (35%).

Acetaminophen is usually well tolerated though skin rash and other allergic reactions exhibited by localized areas of erythema or urticaria occur occasionally. The most serious toxic effect of acute overdosage of acetaminophen is a dose-dependent, potentially fatal hepatic necrosis (34). Studies have demonstrated that as little as 4 g/d of acetaminophen (eight extra-strength tablets) can produce severe liver injury.

When toxic doses are ingested, the ability to glucuronidate acetaminophen is exceeded, shifting metabolism to the microsomal enzyme system (microsomal enzyme oxidizing system)-dependent *N*-hydroxylation to form *N*-acetyl-*p*-benzo-quinoneimine (NABQ) (30). NABQ usually reacts with

sulfhydryl groups in glutathione to form an inactive product. Because of the limited amount of hepatic glutathione, excess NABQ reacts with sulfhydryl groups in hepatic proteins, producing cellular damage and hepatic necrosis.

Early signs of liver toxicity include nausea, vomiting, and abdominal pain. Clinical signs of liver damage may become apparent within 2 to 4 days of ingestion of toxic doses (35). Regular consumption of ethanol can induce hepatic cytochrome P-450, leading to increased oxidative metabolism of acetaminophen to NABQ and lowering the threshold for acetaminophen-induced liver damage (36). Alcoholics may also exhibit hepatic glutathione depletion, which can further increase the severity of liver injury.

Treatment of overdose with acetaminophen requires vigorous supportive therapy, including procedures to limit continued absorption of the drug such as induction of vomiting or gastric lavage, followed by oral administration of activated charcoal. Hemodialysis, if it can be initiated within the first 12 hours, has been advocated for all patients. Administration of sulfhydryl compounds, such as *N*-acetyl cysteine, increases the hepatic content of glutathione, potentially reducing the availability of free NABQ (37).

Renal tubular necrosis can result from long-term abuse of analgesic formulations containing acetaminophen (38). This nephropathy results from *p*-aminophenol, a metabolite of acetaminophen, which concentrates in the hypertonic renal papillae. Renal papillary necrosis occurs as a result of *p*-aminophenol-induced depletion of reduced glutathione.

### Ketorolac

Ketorolac differs from the previously mentioned agents in that, although it is a potent inhibitor of COX I and COX II, it is used primarily as a potent analgesic, usually postoperatively as an alternative to narcotic analgesics (39). Ketorolac is rapidly absorbed orally or intramuscularly with peak blood concentrations within 30 to 50 minutes and with a half-life of 4 to 6 hours. It is highly bound to plasma proteins (98% to 99%) and is metabolized in the liver by conjugation with glucuronic acid; about 60% is excreted unchanged (40). Ketorolac is a potent inhibitor of COX I and COX II and retains the properties of being analgesic and antipyretic. Although these actions would predict a role in inflammation, the recommended short-term therapy with ketorolac precludes its use for this purpose.

Short-term therapy and administration of the lowest effective dose help to avoid adverse effects, which can be severe (41). Gastrointestinal bleeding and perforation and reduced hemostasis due to platelet inhibition have been reported. Although renal impairment has been associated with administration of ketorolac, recent studies indicate this is not significant when adhering to the above dosage guidelines. Elderly patients may exhibit a lower threshold for adverse effects. Dosage is not an issue with administration of ketorolac to asthmatic patients, patients with nasal polyposis, or those with aspirin sensitivity. Such hypersensitivity reactions can lead to life-threatening bronchospasm (42).

## NARCOTIC ANALGESIC AGENTS

Agents with morphinelike actions (opiates) are known as narcotic analgesics and are used for the treatment of all types of severe pain. The broad spectrum of actions mediated by opiate receptors predicts the use of these agents in multiple clinical settings. For example, selected natural and synthetic opiates are used not only in the management of pain but also in the treatment of cough, diarrhea, and dyspnea due to acute left ventricular failure and also as anesthetic and adjunctive anesthetic agents.

Narcotic analgesic and antagonist agents are classified based on their source or actions at the opiate receptor. The *naturally occurring* opiates are derived from the exudate of the seed pod of the opium poppy, which contains more than 20 alkaloids, including morphine and codeine. A second classification based on source is the synthetic opiates derived from commercial synthesis and accounts for more than 20 different compounds with varying therapeutic properties. The classification based on action at opiate receptor includes full agonists, partial agonists, agonist-antagonists, or full antagonists. The action at the opiate receptor in large part determines their clinical use.

### The Opiate Receptor

In 1973, radioligand-binding techniques demonstrated the presence of an “opiate” receptor (43–45). Binding of ligands to these receptors explained the diverse pharmacologic effects of opiate agonists and antagonists (46). High concentrations of these receptors were demonstrated in areas of the CNS known to involve pain signal transmission, including the dorsal horn of the spinal cord, periaqueductal gray, the rostral ventral medulla, and several thalamic nuclei (47). Additional properties included structural specificity—small modifications of the drug molecule cause large changes in drug binding (and in drug effect *in vivo*); stereospecificity—only the *L*-isomeric form of the agent binds with high affinity (and is active as an analgesic); competition between agonists and antagonists—drugs of partially similar structure can bind to the receptor and block binding of agonists such as morphine; reversibility—bound drug can be displaced from the receptors by an excess of other molecules that possess binding affinity; and binding affinity versus efficacy—a good correlation exists between the affinity for binding to the receptors and potency of agonist or antagonist *in vivo* (48).

During the series of studies characterizing the opiate receptor, it became clear that a single receptor could not account for the diverse pharmacologic effects of opiates such as morphine (49). Based on the use of selective agonists, the effects of narcotic analgesics could be differentiated into responses unique to three different opiate receptor subtypes: the mu ( $\mu$ ), delta ( $\delta$ ), and kappa ( $\kappa$ ) opiate receptors (50,51). All three receptors are members of the G-protein-coupled family of receptors and show significant amino acid sequence homologies (52,53). Receptor selectivity profiles have subsequently revealed the presence of subtypes of each of these receptors including  $\mu_1$ ,  $\mu_2$ ;  $\delta_1$ ,  $\delta_2$ ; and  $\kappa_1$ ,  $\kappa_2$ ,  $\kappa_3$  (51).

### Endogenous Opiate Peptides

The discovery that opiate receptors could be demonstrated in “naïve” tissues suggested the existence of endogenous morphinelike compounds that interacted with the receptor. Three families of opiate peptides, or *opiopeptides*, were subsequently discovered that are derived from distinct precursor polypeptides and located in neuronal pathways that mediate nociceptive signaling (54–57). *Beta endorphin* is a large peptide split off enzymatically from proopiomelanocortin; it is concentrated in the pituitary and hypothalamus and is located in areas around the third and fourth ventricles. During painful episodes,  $\beta$  endorphin is released into the cerebrospinal fluid (CSF). *Enkephalins* (methionine enkephalin, leucine enkephalin) are pentapeptides, breakdown products of proenkephalin; based on localization in primary afferent nerve endings, they appear to regulate transmitter release, thereby inhibiting transmission of pain stimuli. *Dynorphins* are formed from prodynorphin and share many of the properties of the enkephalins, especially being localized within nerve endings of CNS pain pathways.

These peptides bind with high affinity to opiate receptor subtypes (Table 66-1), and binding to the receptor is reversed by narcotic antagonists. In addition, these agents demonstrate cross-tolerance to narcotic agonists, and dependence is produced with chronic administration. Moreover, a withdrawal reaction is induced by the administration of narcotic antagonists in animals made dependent by chronic administration of the endogenous opiate peptides (57,58).

Clinically used opiates such as morphine produce their analgesic effects through activation of the opiate receptor subtypes. The pharmacologic profile of these agents indicates multiple actions at the receptor, including full agonist, agonist-antagonist, and partial agonist actions. The receptor activation profile is listed below. It is noteworthy that, in the presence

**TABLE 66.1** Characteristics of Opiate Receptor Subtypes

Receptor	Agonist Ligands	Action
Mu ( $\mu$ )	Morphine	Supraspinal analgesia ( $\mu_1$ )
	Synthetic opioids	Euphoria ( $\mu_1$ )
	Endorphins	Miosis ( $\mu_1$ )
		Spinal analgesia ( $\mu_2$ )
		Respiratory depression ( $\mu_2$ )
		Physical dependence ( $\mu_2$ )
		Constipation ( $\mu_2$ )
Kappa ( $\kappa$ )	Dynorphins	Spinal analgesia
		Supraspinal analgesia
		Miosis
		Sedation
Delta ( $\delta$ )	Enkephalins	Spinal analgesia
		Modulates $\mu$ receptor activity

**TABLE 66.2** Summary of Actions at Opiate Receptors

Compound	Mu ( $\mu$ )	Delta ( $\delta$ )	Kappa ( $\kappa$ )
Morphine	Ag	Ag	Ag
Fentanyl	Ag	Ag	Ag
Methadone	Ag		
Pentazocine HCl	pAg		Ag
Butorphanol tartrate	pAg		Ag
Nalbuphine HCl	Ant		Ag
Buprenorphine HCl	pAg		
Naloxone HCl	Ant	Ant	Ant

Ag, agonist; Ant, antagonist; pAg, partial agonist.

Modified from Reisine T, Pasternak G. Opioid analgesics and antagonists. In: Hardman JG, Limbird LE, Molinoff PB, et al., eds. *Goodman and Gilman's the Pharmacological Basis of Therapeutics*. 9th ed. New York, NY: McGraw-Hill; 1996:521–556, with permission.

of morphine, the agonist-antagonists or partial agonists can function as antagonists to the actions of morphine. The actions of these agents at the receptor subtypes in large part indicate how they are used in the clinical setting (Table 66-2).

### Pharmacokinetics

Depending on the agent, oral absorption of opiates is variable owing to first-pass metabolism in the liver. For example, the bioavailability of morphine following oral administration is only 25% (59). There is also great variability among patients with regard to both blood levels achieved and the rate of elimination. Absorption following intramuscular administration is usually complete, with maximum blood levels achieved within 15 to 30 minutes. Transdermal and epidural administration of opiates are also quite effective (60). Codeine and oxycodone demonstrate good oral-to-parenteral potency ratios due to less first-pass metabolism. In large part, this is due to structural protection from conjugation with glucuronic acid. Meperidine is well absorbed from all routes of administration; about 50% escapes first-pass metabolism following oral administration.

Although distribution to tissues is based largely on blood flow, the levels in the CNS are determined by the blood-brain barrier and the lipid solubility of the agent. For example, whereas a relatively small amount of morphine penetrates into the CNS, the more lipid-soluble fentanyl and its congeners penetrate much more readily (61). Protein binding of the various agents also influences the amount that enters the CNS. For example about 30% of morphine is protein bound and thus unavailable for penetration into the CNS. This compares with about 10% protein binding for codeine, 60% for meperidine, and 90% for methadone.

Most of the opiates are metabolized in the liver to form water-soluble conjugates that are eliminated by the kidney. For example, very little morphine is excreted unchanged, with most appearing as the inactive morphine-3-glucuronide and the active metabolite morphine-6-glucuronide. The morphine-6-glucuronide has actions that are very similar to morphine and

may account for the prolongation of analgesia with morphine administration (62). The glucuronides are eliminated through glomerular filtration and excretion in the urine.

A potentially fatal interaction may occur as a result of coadministration of meperidine and monoamine oxidase inhibitors (MAOIs) (63). Meperidine is *N*-demethylated in the liver to normeperidine and then to normeperidine acid with subsequent conjugation. MAOIs inhibit a step in the metabolism, leading to normeperidine accumulation, which causes excitation, hyperpyrexia, and seizures (64).

## Pharmacologic Actions

### Cellular Effects

All the actions of opiates are mediated by binding to opiate receptors at presynaptic or postsynaptic sites in the CNS, or tissues in the periphery. These agonists produce their unique effects by binding to receptors in tissues that mediate therapeutic (or side effect) outcomes. For example, agents such as morphine produce their analgesic effects by binding to receptors located in nociceptive neuronal pathways in the brain and spinal cord; constipation, a side effect of morphine administration, results from binding to opiate receptors in gastrointestinal smooth muscle. It is binding to these receptors, which results in common therapeutic and side effects among the opiate-narcotic analgesic group of agents. Effects do vary quantitatively, however, among the various agents.

At the cellular level, opiate receptors are coupled to guanosine triphosphate (GTP)-binding proteins, leading to inhibition of adenylate cyclase at both presynaptic and postsynaptic sites (65). Presynaptically, a reduction in voltage-gated  $\text{Ca}^{2+}$  influx reduces excitatory neurotransmitter release (66). Postsynaptic actions include increased  $\text{K}^{+}$  efflux through activation of receptor-operated  $\text{K}^{+}$  currents, leading to hyperpolarization and a reduction in neuronal firing rate (67). The fact that these actions alter signaling in a number of different neurotransmitter systems accounts for the multiple effects of the narcotic analgesics at various central and peripheral sites.

### CNS Effects

Analgesia results from the inhibition of nociceptive reflexes at both spinal and supraspinal sites, primarily by interacting with  $\mu$  receptors. The threshold for pain perception is raised, and the reaction to the pain is reduced (even though pain is perceived). Continuous dull pain is relieved more effectively than sharp, intermittent pain. Components of the CNS nociceptive actions include sedation and alteration in mood, including a reduction in anxiety, a feeling of euphoria, a feeling of being detached, and a “floating” sensation.

Narcotic analgesics produce dose-dependent *respiratory depression* by decreasing the sensitivity of the respiratory center chemoreceptors to  $\text{CO}_2$ . Decreases in rate, minute volume, and tidal exchange are all possible with administration of opiates (68). Separate central effects include miosis resulting from increased activity in the parasympathetic nerve innervating the pupil. *Nausea and vomiting* can occur with opiate

administration and are a result of direct stimulation of the chemoreceptor trigger zone for emesis, in the area postrema of the medulla. All clinically useful  $\mu$  agonists produce some degree of nausea and vomiting and may involve a vestibular component because the incidence is much lower in recumbent patients. *Cough suppression* is a useful side effect and results from direct depression of the cough center in the medulla. Both codeine and dextromethorphan, the nonaddicting D-isomer of the codeine analog levallorphan, are used clinically as antitussives. Finally, truncal *muscle rigidity* may occur with high doses of opiates, especially the highly lipid-soluble agents such as fentanyl. This side effect appears to result from enhanced tone in large trunk muscles, probably owing to increased impulse activity in dopaminergic pathways (69).

### Peripheral Effects

At therapeutic doses, the opiates produce minimal effects on the cardiovascular system (blood pressure, cardiac rate and rhythm) in the supine patient. However, morphine does reduce baroreceptor mechanisms, producing arteriolar and venous dilation, which results in *orthostatic hypotension*. This may be complicated by morphine-induced histamine release and resultant vasodilation. *Histamine release* may also lead to cutaneous flushing, itching, and loss of body heat (hypothermia). Depending on the agent, bronchoconstriction and hypotension may occur as a direct result of the histamine release (70).

The presence of opiate receptors in smooth muscle accounts for significant effects of agents such as morphine on tone and motility in intestinal, biliary tract, ureter, and urinary bladder smooth muscle. Large and small intestine smooth muscle tone is increased and propulsive contractility decreased. Although these actions produce *constipation* as the most common side effect, it is a desirable outcome in patients with diarrhea or irritable bowel syndrome. Constriction of biliary smooth muscle and the sphincter of Oddi in the biliary tract leads to increased biliary tract pressure (*biliary colic*) (71). In addition, opiate-induced increases in tone in the ureter, detrusor muscle of the urinary bladder, and vesicle sphincter can produce *urinary retention*. Combined with a lack of appreciation that the bladder is full, urinary retention is a particularly problematic side effect of opiate administration.

## Tolerance and Physical Dependence

The repeated and continued administration of morphine and other opiates results in the development of tolerance to both therapeutic and side effects of these agents. As a result, increasing dosages are required to produce quantitatively the same effect. Tolerance is gained to analgesic, euphoric, sedative, and respiratory depressant effects, but not to the miotic and constipating effects (72). Less tolerance is gained to the agonist-antagonist agents; tolerance develops more slowly and to a lesser degree to methadone, which is why it is used in opiate abuse treatment programs. Chronic administration of all of the narcotic analgesics results in the development of tolerance; the degree to which tolerance is gained varies according to the percentage of action as an agonist (full agonist > agonist-antagonist > partial agonist).

Cross-tolerance occurs across the spectrum of agents that are full agonists.

Chronic agonist treatment leading to down-regulation of opiate receptors results in attenuation of opiate responses (73,74). It is unclear how this down-regulation occurs; however, constant availability of agonist has been demonstrated to induce phosphorylation of the opioid receptor, thereby inducing desensitization (75). Receptor desensitization most likely involves an interaction between multiple neurotransmitter systems, as suggested by studies that demonstrated inhibition of morphine tolerance and dependence by agents that, for example, block NMDA receptors (76).

Without the continued presence of agonist at the receptor site, the cellular processes linked to the receptor become hyperexcitable, leading to characteristic withdrawal or abstinence syndrome. Withdrawal can also be precipitated in a dependent individual by administering a narcotic antagonist that accomplishes the same outcome.

### Interactions

Adverse reactions may occur with the administration of opiates in individuals with particular disease or injury states and those taking certain drugs. Because of the effects of opiates to depress respiration, caution should be used in patients with pulmonary disease and those with head injuries. In the latter case, after intravenous or intramuscular administration, opiates may lead to an increase in CO<sub>2</sub>, thereby increasing cerebral blood flow and intracranial pressure to exacerbate the injury (77). Because of the dependence on the liver for metabolism and termination of action, opiate dosage may need to be adjusted in patients with liver disease. Finally, patients with pancreatitis may experience a further increase in biliary tract pressure owing to effects of the agents on biliary smooth muscle tone.

Combined administration of narcotic analgesics along with CNS depressants (barbiturates, antianxiety agents, antipsychotics) results in potentiation of the sedative effects of opiates. As mentioned earlier, meperidine administered to patients taking MAOIs can produce excitation, convulsions, hyperpyrexia, respiratory depression, and hypotension.

### Toxicity

Acute overdosing with opiates produces what has been described as the “triad” of symptoms, including depressed respiration, pinpoint pupils (except with meperidine), and coma (78). The first step in treatment is to establish an airway for ventilatory support and attempt to stabilize the cardiovascular system. Administration of a narcotic antagonist will reverse all of the effects of the opiate but may also precipitate withdrawal in dependent individuals.

### Narcotic Antagonists

Opiate (narcotic) antagonists block or reverse all of the actions of the opiate agonists by displacing the agonists from the opiate receptors. A full antagonist binds to the  $\mu$ ,  $\kappa$ , and  $\delta$  opiate receptors (affinity) but has no action or effect on the receptor (efficacy) (69). The three agents classified as full antagonists

are naloxone (half-life, 1 to 2 hours), nalmefene (half-life, 8 hours), and naltrexone (half-life, 10 hours). Naloxone due to extensive first-pass metabolism is administered intravenously for reversal of agonist-induced adverse effects. Naltrexone is administered orally and effectively blocks the euphorogenic effects of opiates for up to 24 hours, thus indicating its use in opiate addiction programs (79).

In the presence of an agonist, antagonism at opiate receptors is also observed for mixed agonist-antagonists such as nalbuphine. Nalbuphine is an antagonist at  $\mu$  receptors and an agonist at  $\kappa$  receptors (see Table 66-2). Pentazocine has weak antagonist actions at  $\mu$  receptors and moderate agonist actions at  $\kappa$  receptors. Butorphanol is similar to pentazocine but more potent as an agonist at  $\kappa$  receptors. Partial agonists, such as buprenorphine, can also function as antagonists in the presence of morphine because they have greater affinity for  $\mu$  receptors and do not activate the  $\kappa$  or  $\delta$  receptors (80). Apparently, the partial agonist can sterically hinder morphine from binding to the full complement of receptor.

The actions of antagonists, agonist-antagonists, and partial agonists have the potential to reverse the beneficial effects of agonists such as morphine when attempting to antagonize adverse side effects such as respiratory depression (81). As a result, analgesia may be “unmasked” as well as sedation. An increased incidence of postoperative nausea and vomiting has been reported with the use of these agents. Precaution should be taken with regard to the half-life of the antagonist versus agonist, especially because the half-life of naloxone is only 1 to 2 hours versus the longer half-life of agonists. All of the agents with antagonist activity may precipitate withdrawal in dependent patients and in the fetus of narcotic-dependent pregnant patients (82).

# Injection Procedures

Injection of medications in proximity to nerves, muscles, and skeletal structures (bursae, joints, and tendons) provides an important intervention in the management of pain and dysfunction. These medications can provide analgesia, reduce inflammation of the affected structure, and promote tissue healing directly and indirectly through facilitation of rehabilitation. Commonly, local anesthetics are used for immediate anesthesia and analgesia, corticosteroids are used to control inflammation, radiopaque contrast is used to assist any fluoroscopic confirmation, and vasoconstrictors are used to prolong local anesthetic effects or warn of intravascular injection. Injection techniques constitute both diagnostic and therapeutic modalities in many settings. As in all patient care, the origin of pain or dysfunction involves careful history taking and a complete physical examination. The details of these techniques are addressed generally in Chapter 2 with a specific focus in Chapters 32, 33, 35, 49, and 68. This chapter first outlines the historical development and general principles of proper procedural techniques, including indications and contraindications. Significant side effects or complications and commonly used medications are reviewed. General techniques for nerve blocks and specific nerve blocks are then discussed.

## HISTORICAL

Since antiquity, sharp objects have been used to inject various concoctions into the body as remedies for pain and dysfunction (1). The tools of modern-day injection procedures include the hollow needle developed by Rynd in 1845 (2) and the syringe developed by Pravaz in 1853 (3) and Wood in 1855 (4). Medications to inject for anesthesia were developed in the late 1800s, with extensive use of cocaine as a topical analgesic (5) and as an injected analgesic (6). The application of these devices and medications to achieve local anesthesia for relief of pain was described by Corning in 1894 (7). Historical information on neural blockade has been reviewed in detail by Brown and Fink (1).

Since the early 1900s, procaine had been injected into the synovium of inflamed joints for temporary relief of pain. In 1949, Hench (8) introduced systemic corticosteroids to suppress the inflammatory changes in rheumatoid arthritis. However, large doses of corticosteroids given systemically resulted in complications. In 1951, Hollander (9) introduced and reported on low-dose local (intraarticular and

periarticular) injections of hydrocortisone acetate to control pain and inflammation caused by trauma and inflammatory joint disease. Historical information on intraarticular injection has been reviewed in detail by Hollander and colleagues (10).

Tender points in the muscle were identified in the 1800s by multiple investigators (11,12). Kraus in 1937 (13) and Travell in 1942 (14) introduced the treatment of myofascial pain by direct trigger point injection and use of vapocoolant spray and emphasized the importance of exercise in the treatment of patients with trigger point mediated pain. Historical information on myofascial pain has been reviewed in detail by Simons (11).

## GENERAL

The general principles for use of neural blockade were described in detail by Bonica in 1953 (15). Injections of local anesthetic agents have been shown to be effective in managing patients with acute and chronic pain. The mechanism of action is the blockade of nociceptive input along the pathway of transmission (16). Intraarticular and periarticular injections of corticosteroids have been shown to reduce inflammation and pain as well as to facilitate mobility and function (17). Unfortunately, injection of medication is often used in isolation for the management of many pain problems. It is important to use injections as one component in a vast armamentarium of techniques that are often best used in concert with each other. An injection unaccompanied by physical therapy, exercise, stretching, behavior modification, and optimization of coexisting psychological disorders is often incomplete in alleviating pain or restoring function. This is best demonstrated by the “block clinics,” which were highly popular in the 1930s and 1940s but have since been superseded by multidisciplinary pain clinics. Injection procedures should be performed within the context of comprehensive rehabilitation.

## Knowledge and Training

Using injection procedures requires sufficient knowledge to understand the diagnosis and treatment of pain syndromes. Limitations, complications, advantages, and disadvantages of each procedure and alternative treatments must be understood when choosing the best therapy or combination of therapies. The practitioner must be highly skilled in injection techniques based on education, training, and experience. This requires a

thorough knowledge of the anatomic basis of the procedure and the characteristics of the injectable medication, including expected side effects of the procedure as well as potential complications and their prevention and prompt treatment (16).

### Contraindications

Injection procedures encompass a wide variety of techniques, including epidural, caudal, nerve, motor point, joint, and muscle. Although relative advantages and disadvantages exist, certain conditions comprise contraindications to perform any injection technique. Certain medical conditions also may preclude an injection. For example, a patient with severe lung disease should not have a rib block with its attendant risk for pneumothorax.

#### Absolute Contraindications

Absolute contraindications for injection procedures include patient refusal, localized infection, dermatologic conditions that preclude adequate skin preparation, existence of a tumor at the injection site, history of allergy to local anesthetic agents, the presence of severe hypovolemia, gross coagulation defects, increased intracranial pressure (for epidural procedures), and septicemia.

#### Relative Contraindications

Among relative contraindications are the lack of education, training, and skill on the physician's part. In addition, relative contraindications are the patient's minor coagulation abnormalities or concurrent use of certain anticoagulants such as minidose heparin. Diabetes is a relative contraindication for injections with corticosteroids because of the possibility of hyperglycemia, glycosuria, electrolyte imbalance, and increased risk for infection.

#### Screening for Contraindications

Early in the interview process, the patient should be asked specific questions about conditions that would preclude the injection procedure. Firstly, anticoagulation issues must be addressed, and the patient should have been able to discontinue antiplatelet therapy (e.g., clopidogrel) or anticoagulation (e.g., unfractionated heparin or warfarin) for sufficient duration. The practitioners should be aware of current guidelines regarding anticoagulation and neuraxial procedures and have developed a standard practice ahead of time in regards to anticoagulation and injections. Secondly, the patient should have transportation and a responsible adult who can care for the patient after the procedure, especially if the injection has the potential to cause weakness or sedation. Thirdly, the patient should be appropriately fasted to reduce the chance of aspiration, particularly if he or she is likely to need sedation. Any allergies to the expected injection medications or to material such as latex should be documented and alternatives be used for the procedure.

### Communication

Communication with the patient is essential at all steps involved in patient care, including injection. Providing the

patient with a complete explanation of the procedure will result in the individual having increased confidence and reduced anxiety. During the procedure, the physician should continually inform and reassure the patient as to the progress of the procedure.

### Informed Consent

Although state laws vary in terms of the documentation required, informed consent involves providing enough information about the injection procedure so that the patient can intelligently decide whether or not to proceed (without external coercion or manipulation). This involves a thorough discussion of the procedure with the patient, including the possible benefits, alternative treatments, common side effects, and risks of complications. The patient should be given the opportunity to ask questions about details of the injection. The patient should not receive medications that could significantly impair responses or judgment before the consent is given. Depending on state regulations, the patient may or may not be required to sign an informed consent form. Significant complications of injection procedures are provided in Table 67-1.

### Universal Precautions

Universal precautions are required for all injection techniques to reduce the incidence of transmission of infectious agents (18). These include the use of gloves and protective eye wear. Possible transmission of blood-borne pathogens during medical procedures is a common concern among patients and health care workers, owing to its potentially devastating consequences. Although this concern has largely focused on the human immunodeficiency virus (HIV), other agents, particularly hepatitis B, C, and G viruses, are of significantly greater risk. The data show that the risk to health care workers from patients is far greater than the risk to patients from health care workers (19). It is important that proper sharps disposal containers are maintained in all areas where needles are used. Hollow needle sticks pose the greatest risk for occupational transmission, with studies following health care workers after

such exposures finding the following seroconversion rates: hepatitis B, 5% to 37%; hepatitis C, 3% to 10%; and HIV, 0.2% to 0.8% (19–23). Research shows that recapping a needle increases the risk for needle stick, hence needles should either be laid down in the sterile field or disposed uncapped in an appropriate container.

### Positioning

Optimal results of any injection depend on proper positioning of the patient before, during, and after the injection procedure. The proper position should facilitate access to the injection site, with the patient and provider being as comfortable as possible. Bony prominences should be cushioned where needed to avoid discomfort from pressure. When possible, the recumbent position is used because it is usually the most comfortable for the patient. It also minimizes the incidence of orthostatic hypotension caused by vasovagal reaction during the procedure. Positioning to avoid ergonomic stress on the patient and physician is essential. Consideration should be made for access to special equipment such as a fluoroscopic C-arm or ultrasound machine.

### Skin Preparation

Strict aseptic preparation is required in all injection procedures, as well as intact skin at the site of injection. Preparation of the injection site is undertaken in a standard aseptic fashion over an area large enough to allow palpation of landmarks and any potential extension of the injection site, and sterile technique is used throughout the procedure to minimize the risks. Most injection techniques described in this chapter do not require full surgical draping; however, the phrase “sterile technique is used throughout the procedure” indicates an increased risk for major infectious complications, including epidural abscess, meningitis, and adhesive arachnoiditis.

The injection site is prepared with an antiseptic to reduce cutaneous microorganisms to the lowest level. Commonly used agents include chlorhexidine (Hibiclens, Zeneca Pharmaceuticals, Wilmington, DE), iodophors (Betadine, Purdue Frederick, Norwalk, CT), and alcohol (24). It is important for the clinician to wait about 2 minutes after the application of any of the above antiseptics to obtain maximal reduction in cutaneous bacteria. It is rarely justified to remove hair from the skin for an injection procedure (25). In addition to skin preparation, some procedures such as intradiscal procedures or prolonged catheter trial probably warrant systemic intravenous antibiotics prior to needle insertion (26). Many providers will wear a surgeon's cap, filtration mask, and full surgical gown, although any differences in the rate of infections have been difficult to demonstrate.

### General Procedural Sequence

Informed consent should be obtained from the patient, an intravenous catheter placed if sedation is to be used, and monitors applied (pulse oximeter, noninvasive blood pressure, and 3 to 5 lead EKG) if indicated based on use of sedation or on patient comorbidities. Resuscitation equipment, including

oxygen source, mask and bag for ventilation, suction, code medications, and advanced airway equipment should be readily available. The patient should be properly positioned, and the injection site prepared and draped in standard aseptic fashion over an area large enough to allow palpation of landmarks. All medications, syringes, needles, and other equipment should be readily available. Syringes may vary from 3 to 12 mL. Needles may vary from as small as ½-in. (1-cm), 25-gauge needles to 3½-in. (9-cm), 21-gauge spinal needles. For convenience, an 18-gauge needle should be available to draw medications from the vial. All caregivers participating in the injection procedure should be gloved and practicing universal precautions. An audible “time-out” involving confirmation of the correct patient, injection site, and injection side (if applicable) should be performed. Then, as the procedure is underway, there should be periodic communication with the patient to screen for any problems, such as severe pain from the needle, signs of local anesthetic toxicity, paresthesias, etc. After the injection is complete, the patient should be monitored afterward for any side effects, and reexamined to evaluate for proper distribution and efficacy of analgesia. Discharge instructions should be given to the patient including symptoms to expect, symptoms which warrant calling a nurse or physician, activity restriction (if any), follow-up scheduling, and personal log to record duration and intensity of pain relief.

### Needle Insertion

To reduce pain of the initial needle insertion, the skin may be stretched while rapidly piercing the skin. Once the skin is pierced, the tension is released and the needle is advanced slowly. Rapid infusion of medication may result in tissue distention, causing pain. Other methods of reducing pain with initial needle insertion include the use of topical anesthetics and vapocoolant sprays.

### Conscious Sedation

The procedures described in this chapter rarely require conscious sedation. In circumstances in which conscious sedation is used, monitoring should be applied to the patient as previously described, and advanced airway management tools should be readily available. Resuscitation equipment, medications, and personnel must be readily available. Any prior sedation records should be reviewed for previous sedation dose requirements and any anesthetic complications.

## MEDICATIONS

Injection procedures use three primary classes of medication: local anesthetic agents, neurolytic agents, and corticosteroids. All of these medications have multiple clinical applications and are documented to be safe and effective when used appropriately. It is incumbent on the practitioner to understand the efficacy, complications, and common side effects of these agents.

## Anesthetic Agents

The mechanism of local anesthetic action is a reversible block of ion flux through the axon's sodium channels. By blocking transmission from the peripheral nerves, no input is detected at the central nervous system (CNS). The degree of neural blockade depends on the properties, absorption, amount, location, and other characteristics of the drug injected (28,29) (Table 67-2). For purposes of attaining longer duration analgesia, agents such as bupivacaine or ropivacaine are acceptable and safe when used within the dosing guidelines. Anesthetic agents with fast onset, such as lidocaine, are useful particularly for skin infiltration prior to block insertion or for rapid diagnosis of the pain generator site. Local anesthetics should be chosen appropriately for both the purpose and the site of injection. For example, commercial preparations may come with preservatives, making them potentially neurotoxic if given intrathecally. Therefore, it is imperative to verify that the particular medication preparation is approved for the desired use. This information is available in many locations, including the package insert for the medication.

When higher doses of local anesthetics are used (i.e., near the upper limit of recommended dose), are injected near highly vascular structures (face, intercostals), or injected near the

neuraxis (paravertebral, epidural, or intrathecal), monitoring of the patient is highly recommended. Verbal communication, constant screening for symptoms, and pulse oximetry can identify any CNS toxicity, while the electrocardiogram and blood pressure can identify any cardiovascular toxicity. If signs of toxicity or high spinal block are present, injection should be suspended and the patient closely evaluated and/or supported.

## Neurolytic Agents

Neurolytic nerve blocks were popular in the early 1900s. However, improved use of analgesics, as well as the use of radiofrequency and cryoablative techniques, has replaced their use in most instances. Alcohol and phenol are the most widely used neurolytic agents in the United States. These agents indiscriminately affect motor and sensory nerves.

Phenol can be used intrathecally and epidurally, as well as for peripheral nerve and motor point blocks. It is poorly soluble in water and is often added to glycerin to achieve concentrations higher than 7%. It also can be added to radiographic contrast to allow fluoroscopic visualization of the spread during injection. Phenol has a local anesthetic effect, resulting in less pain after the injection. Because of this, long-term effects

of the block cannot be evaluated for 24 to 48 hours after the effects of the local anesthetic dissipate. Doses greater than 100 mg can result in serious toxicity (30).

Alcohol is used primarily intrathecally for nerve roots and locally for sympathetic blockade. Patient positioning with intrathecal use is extremely important, because alcohol is hypobaric in cerebrospinal fluid (CSF). It is readily soluble in body tissues and produces intense burning on injection. It requires 12 to 24 hours before block effects can be determined.

### Corticosteroids

Glucocorticosteroids are used in the injection treatment of inflammatory processes (31) (Table 67-3). Some of the commonly used forms of corticosteroid available for intraarticular injections are listed as follows:

- Betamethasone sodium phosphate and acetate (Celestone Soluspan), 6 mg/mL
- Methylprednisolone acetate (Depo-Medrol), 40 and 80 mg/mL
- Prednisolone sodium phosphate (Hydeltrasol), 20 mg/mL
- Prednisolone terbutate (Hydeltra-TBA), 20 mg/mL
- Triamcinolone acetonide (Kenalog), 40 mg/mL
- Triamcinolone hexacetonide (Aristospan) 20 mg/mL

These corticosteroids vary in strength, concentration, duration, and side effects, and all are effective. Triamcinolone hexacetonide has the longest duration of suppression of inflammatory activity. Fluorinated corticosteroids (e.g., triamcinolone) are rarely chosen for soft-tissue injection, because they are more likely to cause tissue atrophy. Prednisolone tebutate and methylprednisolone acetate are often used for soft-tissue injections because of their efficacy and cost.

### SIDE EFFECTS AND COMPLICATIONS

The injection procedures described here are associated with various side effects, although the risk for significant complications is very low. The physician who performs injection procedures should have the training and education to recognize and treat a wide range of potential complications (Table 67-4). Advanced cardiac life support (ACLS) protocols are used in airway management and cardiorespiratory resuscitation (27).

### Systemic Toxic Reaction

Various toxic reactions have been reported after use of local anesthetics, but with very low incidence. Local anesthetic agents are relatively lipid-soluble, low-molecular-weight compounds that readily cross the blood-brain barrier. As toxic levels are reached, disturbances of CNS function are observed initially, producing signs of CNS excitation. Early symptoms of overdose include headache, ringing in the ears, numbness in the tongue and mouth, twitching of facial muscles, and restlessness. As blood levels increase, generalized tonic-clonic seizures may occur. If sufficiently high blood levels are reached, the initial excitation is followed by generalized CNS depression. Respiratory depression and ultimately respiratory arrest may occur secondary to the toxic effect of the local anesthetic agent on the respiratory center in the medulla. Occasionally, the excitatory phase may not occur, and toxicity presents as CNS depression.

Cardiovascular system (CVS) effects either result indirectly from inhibition of autonomic pathways during regional anesthesia (as in high spinal or epidural block) or are directly due to depressant actions on the CVS. The CVS is generally

**TABLE 67.4 Differential Diagnosis of Local Anesthetic Reactions**

<b>Etiology</b>	<b>Major Clinical Feature</b>	<b>Comments</b>
Systemic toxic reaction		
Intravascular injection	Immediate convulsion and/or cardiac toxicity	Injection into vertebral or a carotid artery may cause convulsion even with administration of small dose
Relative overdose	Onset in 5–15 min with irritability, progressing to convulsions	
Epinephrine reaction	Tachycardia, hypertension, headache, apprehension	May vary with vasopressor used
Vasovagal reaction	Rapid onset	Rapidly reversible by elevating the legs and discontinuing the noxious stimulus
	Bradycardia Hypotension Pallor, faintness	
Allergy	Anaphylaxis (↓ blood pressure, bronchospasm, edema)	Allergy to amides extremely rare
Immediate		Cross-allergy, e.g., with preservatives in local anesthetics and food
Delayed	Urticaria	
High spinal or epidural	Gradual onset Bradycardia <sup>a</sup> Hypotension Possible respiratory arrest	May lose consciousness with total spinal block; onset of cardiorespiratory effects more rapid than with high epidural or with subdural block
Concurrent medical episode (e.g., asthma attack, myocardial infarct)	May mimic local anesthetic reaction	Medical history important

<sup>a</sup>Sympathetic block above T-4 adds cardioaccelerator nerve blockade to the vasodilatation seen with blockade below T-4; total spinal block may have rapid onset.

From Covino BG. Clinical pharmacology of local anesthetic agents. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 2nd ed. Philadelphia, PA: JB Lippincott; 1988:134, with permission.

more resistant to toxicity than the CNS. The CVS-to-CNS toxicity ratio is lower for bupivacaine and etidocaine than for lidocaine. Convulsive activity may initially be associated with an increase in heart rate, blood pressure, and cardiac output. As the blood concentration of a local anesthetic agent increases further, CVS depression occurs, resulting in a decrease in blood pressure secondary to myocardial depression, impaired cardiac conduction, and eventual peripheral vasodilation. Ultimately, circulatory collapse and cardiac arrest may result. In addition, certain agents such as bupivacaine may cause ventricular arrhythmias and fatal ventricular fibrillation. The onset of CVS depression with bupivacaine may occur relatively early and be resistant to usual therapeutic modalities. The pregnant patient is more sensitive to the cardiotoxic effects of bupivacaine.

Systemic toxicity may be due to unintentional intravascular injection or drug overdose. Intravascular injection produces signs of toxicity (usually seizures) during the injection itself, especially if injected directly into blood vessels supplying to the brain (e.g., vertebral arteries). A relative overdose results in toxic reactions when peak blood levels are reached, about 20 to 30 minutes after the injection. Factors that affect the blood concentration (site of injection, drug, dosage, addition of vasoconstrictor, speed of injection) influence the potential for systemic toxic reactions to develop.

To minimize systemic reactions to local anesthetic agents, intravascular injection (the most common cause of seizures)

should be avoided. Careful, intermittent aspiration should be used while injecting large quantities of local anesthetic agents. Patient complaints of metallic taste, numbness around the mouth, and ringing in the ears are suggestive of intravascular needle placement. Patients may be premedicated with midazolam or diazepam to raise the seizure threshold if necessary.

Systemic toxicity is treated with general supportive measures. If early signs of toxicity occur, constant verbal contact should be maintained, oxygen administered, breathing encouraged, and CVS function monitored. If seizure activity occurs, a clear airway should be maintained and oxygen administered by assisted or controlled ventilation. If seizures continue, thiopental (50 to 100 mg) or diazepam (5 to 10 mg) should be administered intravenously, avoiding large doses of thiopental, which may produce additional CVS or CNS depression. If airway maintenance is jeopardized, succinylcholine should be used to facilitate endotracheal intubation. Muscular convulsive activity is terminated with succinylcholine, but the seizure activity in the brain is not affected. If CVS depression occurs, hypotension should be treated by increasing intravenous fluids, positioning the patient properly (elevate the legs), and using vasopressors such as ephedrine or epinephrine (Table 67-5).

### Epinephrine Reaction

Reaction to epinephrine may sometimes be confused with local anesthetic overdose. Systemic absorption of epinephrine

**TABLE 67.5 Treatment of Acute Local Anesthetic Toxicity**

Airway
Establish clear airway; suction, if required
Breathing
Oxygen with face mask
Encourage adequate ventilation (prevent cycle of acidosis, increased uptake of local anesthetic into CNS, and lowered seizure threshold)
Artificial ventilation, if required
Circulation
Elevate legs
Increase IV fluids if ↓ blood pressure
CVS support drug if ↓ blood pressure persists (see below) or ↓ heart rate
Cardioversion if ventricular arrhythmias occur
Drugs
CNS depressant
Diazepam 5–10 mg, IV
Thiopental 50 mg, IV, incremental doses until seizures cease
Muscle relaxant
Succinylcholine 1 mg/kg, if inadequate control of ventilation with above measures (requires artificial ventilation and may necessitate intubation)
CVS support
Atropine 0.6 mg, IV, if ↓ heart rate
Ephedrine, 12.5–25 mg, IV, to restore adequate blood pressure
Epinephrine for profound cardiovascular collapse

CNS, central nervous system; CVS, cardiovascular system; IV, intravenous.  
 From Covino BG. Clinical pharmacology of local anesthetic agents. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 2nd ed. Philadelphia, PA: JB Lippincott; 1988:135, with permission.

produces palpitations and restlessness about 1 to 2 minutes after completion of the injection. Avoiding epinephrine should be considered in patients who are sensitivity prone (e.g., hypertensive, or hyperthyroid, arrhythmic patients). Epinephrine should not be used for blocks of the fingers, toes, or penis, owing to the possibility of localized vasoconstriction. An epinephrine reaction is treated with a small dose of fast-acting barbiturate to reduce blood pressure to within normal limits. If hypertension persists, a vasodilator may be required.

### Vasovagal Reaction

Vasovagal reaction is a frequent response to injection procedures that is attributable to physiologic and psychological factors. This response may result in bradycardia, hypotension, and loss of consciousness. This usually occurs in the initial portion of the procedure when skin is penetrated before any medication is injected. Vasovagal reaction is often mislabeled as an allergic reaction to the medication. This response is often preceded by dizziness, faintness, sweating, and pallor. Vasovagal reaction is rapidly reversible by removing painful stimuli and placing

the patient in a head down and legs up position to improve venous blood return to the heart. If this fails to relieve the symptoms, then treatment with general supportive measures is indicated, including airway maintenance, oxygen, intravenous fluids, anticholinergics such as atropine, and vasopressors such as ephedrine (see Table 67-5).

### Allergic Reaction

An allergic reaction to local anesthetic agents rarely occurs and in some instances may be confused with a vasovagal reaction or a reaction to epinephrine. Ester anesthetic agents (e.g., procaine, tetracaine) are more frequently associated with allergic reactions than amide anesthetic agents (e.g., lidocaine, ropivacaine), because esters are derivatives of paraaminobenzoic acid (PABA). However, the use of amides from multiple-dose vials may result in an allergic reaction secondary to the preservative methylparaben. Allergic reaction is treated with general supportive measures and the administration of fluids, antihistamine, steroids, and epinephrine (if warranted), as well as removal of any additional offending agent. The patient should be closely monitored for a clear airway.

Although this is a rare event, if there is a question of patient hypersensitivity to anesthetic agents, intradermal skin tests (injection with diluted [1:1,000] followed by undiluted local anesthetic) can be used successfully to diagnose adverse responses. However, false-positive results may occur. Anaphylactic shock is treated as systemic toxic reaction with attention to maintaining cardiovascular and ventilatory function (see Table 67-5).

### Accidental Spinal Block

Inadvertent subarachnoid or epidural blockade can occur with any injection that is performed close to the spine. These injections include intercostal nerve blocks, sympathetic blocks, and nerve root injections. Proper equipment and staff should always be available to treat any possible complication. This includes the ability to administer fluids and vasopressors if the patient develops hypotension from sympathetic blockade and to maintain ventilation with oxygen if the patient has impaired respiratory function.

### Concurrent Medical Episode

Concurrent medical problems may be exacerbated by injection procedures. Hypotension will reduce myocardial perfusion and may be a major factor for reinfarction in patients with ischemic heart disease. Patients with poorly treated hypertension risk developing hypertensive crisis, myocardial infarction, or stroke triggered by the stress of the procedure. Patients with chronic renal failure are more susceptible to toxicity from local anesthetics. Diabetic patients have an increased sensitivity to the effects of corticosteroid injection. Patients with liver disease may have reduced metabolism of local anesthetic medications resulting in an increased possibility of toxicity at standard doses. Other medical illnesses may decompensate clinically, owing to mild toxicity and changes in fluid and electrolyte balance. These risks are minimized

with appropriate monitoring and optimal medication regimes. Patients should be medically stable before undergoing elective injection procedures.

### Infection

Although infectious complications rarely occur, cutaneous and joint infection, epidural abscess, bacterial meningitis, and adhesive arachnoiditis have been associated with injection procedures. Epidural abscess may cause spinal cord compression. Signs and symptoms of epidural abscess are severe back pain, localized tenderness, fever, leukocytosis, cervical rigidity, increased protein and leukocytes in the cerebral spinal fluid, progressive neurologic symptoms, and abnormal imaging studies of the spine. Early diagnosis and prompt treatment are essential to avoid catastrophic complications. Meningitis and adhesive arachnoiditis are the result of the introduction of bacterial or irritating contaminants into the spinal fluid as well as trauma during the procedure.

### Pneumothorax

Injections into the thoracic region have the potential to cause a pneumothorax. In procedures that put the patient at risk for needle penetration of the lung, less than 1% develop a pneumothorax (32,33). Most of these patients can be easily treated with administration of 100% oxygen, close monitoring (e.g.,  $O_2$  saturation, vital signs) of the patient, and, when necessary, needle aspiration of air. Only those pneumothoraces that result in significant dyspnea or those under tension require chest tube thoracostomy and vacuum drainage. Bilateral thoracic procedures should be undertaken with caution due to potential risk of bilateral pneumothorax.

### Nerve Injury

Three major factors contribute to nerve injury during injections: trauma, toxicity, and ischemia, with all three contributing to most nerve injuries. Nerve blocks are the result of infiltration of anesthetic agents around the nerve, not directly into the neural tissue. Intraneural injections directly injure nerve fibers and cause a breakdown in the blood-nerve barrier. The use of short, beveled needles has significantly reduced nerve injuries from injections. Intense pain in the nerve distribution and high resistance upon injection are often the result of intraneural needle placement and necessitate immediate cessation of the injection and repositioning of the needle.

### Other Complications

Local anesthetic agents used in recommended clinical concentrations have minimal irritating effects on the nerves, skin, and subcutaneous tissue. Complete recovery of function occurs after regional blocks. The administration of large doses of prilocaine may lead to methemoglobinemia, owing to the accumulation of a metabolite (OH-toluidine) that can convert hemoglobin to methemoglobin. It may be treated with intravenous methylene blue.

Hypotension may result from sympathetic blockade. This commonly occurs in patients who are hypovolemic and receive a spinal or epidural block involving a large portion of the sympathetic chain ganglia. Hypotension is treated with general supportive measures, including administration of intravenous fluids, vasopressors such as epinephrine to maintain blood pressure within normal limits, and proper positioning (elevating the legs). Bradycardia from blockade of sympathetic outflow from T1-4 may require prompt treatment.

Bleeding at the site of injection occurs commonly at the surface. Hematoma at the site of injection is a possibility but usually not clinically significant. If arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

## COMMON NERVE BLOCK TECHNIQUES

### General

The placement of local anesthetics at various sites along the neural axis is an important tool in the diagnosis and treatment of a variety of pain disorders, such as complex regional pain syndrome and postherpetic neuralgia. Peripheral nerve blocks also can provide muscle relaxation and pain relief to facilitate an active physical therapy program.

When the point of injection has been determined, it is best marked with the tip of a retracted ballpoint pen or a needle hub by pressing the skin to produce a temporary indentation to mark the point of entry. The skin is then prepared in a standard sterile fashion, and sterile technique is used throughout the procedure. The skin and subcutaneous tissue at the injection site may be anesthetized by injecting 1% lidocaine with no epinephrine using a 25- to 30-gauge needle. Alternatively, a vapocoolant spray or analgesic cream applied to the skin surface may be used to provide adequate anesthesia.

Before injecting the medication, an attempt to aspirate should always be made to avoid accidental intravascular injection. After ensuring that the needle is in the joint space, the medication should be injected in a slow, steady fashion.

### Indications for Nerve Blocks

Neural blockade may be used for the diagnosis, prognosis, and treatment of pain. Selective nerve blocks are indicated to determine the etiology of pain by isolation of specific anatomic structures. Selected nerve blockade is used to determine specific nociceptive pathways and other mechanisms involved in pain generation. Diagnostic blocks assist in narrowing the differential diagnosis of the site and cause of pain. Prognostic neural blockade is used to evaluate the possible outcome from neurolytic procedures. Therapeutic nerve blocks are indicated to decrease morbidity in acute postoperative pain, posttraumatic pain, and pain resulting from self-limiting conditions. Nerve blockade may provide rapid relief of pain and facilitate the patient's participation in a comprehensive rehabilitation program. Therapeutic nerve

blocks may interrupt the pain cycle sufficiently to provide prolonged pain relief.

### Contraindications for Nerve Blocks

Absolute contraindications for regional anesthesia include patient refusal, localized infection, a skin condition that prevents adequate skin preparation, the existence of a tumor at the injection site, a history of allergy to local anesthetics, the presence of severe hypovolemia (for blocks that could result in significant sympathetic blockade), gross coagulation defects, septicemia, and increased intracranial pressure (spinal, caudal, and epidural).

Prilocaine should not be used in doses greater than 600 mg, because significant methemoglobinemia may result. The use of corticosteroids with preservatives is contraindicated in epidural and subarachnoid techniques because the preservative may result in seizures and permanent CNS damage.

Relative contraindications include general medical conditions that would put the patient at increased risk. These include aortic stenosis, severe lung disease, sickle cell anemia, and preexisting neurologic diseases such as multiple sclerosis or amyotrophic lateral sclerosis, which could be worsened during regional anesthesia.

### Complications

Complications common to nerve blocks include hypotension from sympathetic blockade. This usually occurs in patients who are hypovolemic and receive a block covering a large portion of the sympathetic chain ganglia, for example, during spinal or epidural blockade. Local anesthetic overdose or intravascular injection can result in CNS toxicity and, in some cases, pulmonary and cardiac arrest. Nerve injury from contact with the needle may occur but is rare, especially when a short, beveled needle is used. Other complications are dependent on the location of the block and are discussed separately.

### Techniques

Before the injection, the appropriate landmarks are located and marked. The skin is scrubbed with antiseptic and allowed to dry for 2 minutes. The wearing of sterile gloves is required so that the bony landmarks in the sterile field may be palpated throughout the procedure. The standard sterile technique is required to minimize the risk for infection. It is preferable to use single-dose vials of the local anesthetic because this further reduces the risk for infection. A 25- to 27-gauge needle is used with 1% lidocaine with no epinephrine to raise a small skin wheal for skin anesthesia. Routinely a 1½-in. (4-cm), 21- to 25-gauge needle transverses the skin, joint capsule, synovial lining and then slides smoothly into the joint cavity.

Aspiration is done to ensure there is no intravascular penetration. If penetration occurs, the needle should be repositioned and aspirated to ensure that blood vessels have been avoided; then the medication is slowly injected. After the medication has been injected, the needle should be cleared with a new syringe containing a small amount of lidocaine or

saline. The needle is then withdrawn with pressure applied to minimize bleeding.

### Nerve Stimulator

Peripheral nerves may be localized with a nerve stimulator using a small adjustable amount of electrical current to depolarize neural tissue in proximity to the needle. The cathode (negative) terminal is connected to the needle, and the anode (positive) terminal is connected to a grounding patch. The stimulator initially is set to deliver 10 to 20 mA of current to detect the general area of the nerve. The current is then reduced to further localize the nerve. The needle is positioned to produce the maximal twitch at the lowest stimulus. The needle is usually adjacent to the nerve when 0.5 to 0.1 mA produces motor stimulation with an insulated needle and 1 mA with an uninsulated needle (Fig. 67-1).

Nerve stimulators do not substitute for knowledge of anatomy and proper needle placement. Insulated needles increase the point of maximal current density at the needle tip and are used for precise localization of specific nerves. Uninsulated needles are often accurate enough for many nerve blocks; however, both the tip and shaft of the needle have sufficient current density to stimulate a nerve. Local muscle twitches from the shaft of the uninsulated needle should not be confused with the response from the nerve to be blocked (Fig. 67-2).

## SPECIFIC NERVE BLOCKS

### Occipital Nerve Block

#### Indication

The occipital nerve blockade is used both diagnostically and therapeutically in the treatment of occipital neuralgia.

#### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the head flexed forward. The occipital nerve is located at the midpoint between the mastoid process and the greater occipital protuberance at the superior nuchal line. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 21- to 25-gauge needle is inserted perpendicular to the superior nuchal line. Before reaching the periosteum of the skull, paresthesias in the occipital nerve distribution may be elicited. If not, the periosteum is contacted and the needle withdrawn slightly. After negative aspiration, 3 to 5 mL of local anesthetic is injected to block the occipital nerve (Fig. 67-3).

#### Comments

Localization of the nerve may be accomplished by palpation of the occipital artery just lateral to the nuchal ridge. The nerve runs with the occipital artery, innervating the posterior portion of the skull. A nerve stimulator may be used for precise needle placement. An alternate approach may be used with the

**FIGURE 67-1.** Nerve stimulator attached to regional block nerve. The negative (*black*) lead is attached to the exploring needle, whereas the positive (*red*) lead is connected to the reference electrocardiogram pad used as the ground reference. Note the current distribution pattern for this uninsulated needle. (From Mulroy MF. *Regional Anesthesia: An Illustrated Procedural Guide*. Boston, MA: Little, Brown; 1989:63. With permission.)

patient positioned as above with anatomic landmarks identified. A 2-in. (5-cm), 21- to 25-gauge needle is inserted subcutaneously along the middle third of the superior nuchal line. After negative aspiration, 5 mL of local anesthetic is injected to block the greater and lesser occipital nerves (see Fig. 67-3).

### Complications

Intravascular injection can occur, resulting in systemic toxicity and seizures, especially if larger volumes are used. Bleeding due to vascular injury also may occur. Nerve injury secondary to injection into the nerve may result in persistent numbness over the posterior portion of the scalp.

### Stellate Ganglion Block

#### Indication

Stellate ganglion blockade is useful for diagnosing and treating pain of sympathetic origin. This includes pain involving the face, head, neck, and upper extremities secondary to complex regional pain syndrome, acute herpes zoster, and phantom limb pain.

#### Techniques

After informed consent is obtained, the patient is placed in the supine position with a pillow under the shoulders and the neck extended. The patient is prepared in a standard aseptic fashion

**FIGURE 67-2.** Current density pattern for insulated and uninsulated needles. (From Pither CE, Raj PP, Ford DJ. The use of peripheral nerve stimulators for regional anesthesia: a review of experimental characteristics, techniques, and clinical applications. *Reg Anesth*. 1985;10:49–58, with permission.)

**FIGURE 67-3.** Occipital nerve block. Approach for occipital nerve block and neural blockade. (From Murphy TM. Somatic blockade of the head and neck. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. Philadelphia, PA: JB Lippincott; 1998:507, with permission.)

over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. The transverse process of the C6 vertebral body is palpated between the cricoid cartilage and the carotid artery. A 1½-in. (4-cm), 22-gauge needle is inserted vertically and advanced to touch the periosteum of the C6 transverse process. The needle is withdrawn slightly, and after negative aspiration, a 1-mL test dose of local anesthetic is injected. After unremarkable test dose and repeated aspiration, 9 mL of local anesthetic is injected, in divided doses with continuous monitoring, to block the stellate ganglion (Fig. 67-4).

### Comments

This technique is commonly used for differential diagnosis and is the preferred treatment of sympathetic mediated pain involving the upper extremity. The stellate ganglion is located between the anterolateral surface of the seventh cervical vertebral body and neck of the first rib. It is formed by the inferior cervical ganglion and first thoracic sympathetic ganglion. Autonomic mediated pain does not usually correspond to segmental or peripheral nerve distribution.

This procedure requires full monitoring capability to include blood pressure, EKG, heart rate, level of consciousness, and pulse oximeter. Temperature should be monitored and recorded for each hand before, during, and after the procedure. The patient is continuously monitored for change

and level of consciousness or for adverse reaction. Successful stellate ganglion blockade is suggested by rising temperature on the block side as well as evidence of a Horner's syndrome (miosis, ptosis, anhidrosis, and enophthalmos). Nasal congestion and hoarseness may occur with this injection. It is recommended that intravenous access be available before the block in the event of intravascular injection resulting in seizure activity or cardiovascular instability (34). Rarely are ablative nerve procedures (neurolysis) recommended in the management of sympathetic mediated pain of the upper extremity.

### Complications

Performance of this procedure outside of a fully monitored environment is not recommended. Resuscitation equipment and personnel must be readily available. Although appearing technically simple, this block has multiple potential hazards, owing to the proximity of the common carotid artery, vagus and recurrent laryngeal nerves, jugular vein, vertebral artery, trachea, esophagus, lung, and dura. Intraarterial and intradural injection of local anesthetic may result in death, seizure, respiratory arrest, cardiac arrest, cerebral damage with multiple sequelae, and other lesser complications. The risk for intravascular injection may be reduced if a test dose is given, the total dose is injected incrementally, and aspiration is performed before each injection.

**FIGURE 67-4.** Stellate ganglion block. Approach for stellate ganglion injection and neural blockade. Cross-section at C6. (From Raj PP. Chronic pain. In: Raj PP, ed. *Clinical Practice of Regional Anesthesia*. New York, NY: Churchill-Livingstone; 1991:495, with permission.)

## Cervical Epidural Steroid Injection

### Indications

Cervical epidural steroid injection (ESI) is primarily used to treat pain arising from cervical herniated discs or spinal stenosis.

### Techniques

After informed consent is obtained, the patient is placed in the prone, lateral decubitus, or sitting position with the neck flexed. The sitting position, with the head resting on the examination table, provides better stabilization of the neck during the procedure but may be a problem if the patient is prone to light-headedness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. Local skin anesthesia is provided with 1% to 2% lidocaine at the C7-T1 interspace. A Tuohy epidural needle is advanced in a midline, horizontal fashion until well seated in the posterior ligaments. A winged needle is preferred because it allows two-handed control of the needle as it is directed toward the epidural space. A midline or paramedian approach may be used, although large epidural veins lie laterally. The stylet is then removed, and a “loss-of-resistance” syringe is attached to the hub of the needle. Two to three mL of air or normal saline should be in the syringe. The needle is slowly advanced 1 to 2 mm at a time, with constant checking for loss of resistance by tapping on the plunger of the syringe. Alternatively, the needle can be advanced slowly and continuously with constant light pressure on the plunger. Once a distinct loss of resistance is obtained, the needle is halted, and

an attempt is made to aspirate blood or CSF. After negative aspiration, 6 mg of betamethasone sodium phosphate and acetate or equivalent is injected. Care should be taken to flush the needle with normal saline and to replace the stylet before the needle is removed to avoid depositing steroid in the needle track to the skin.

### Comments

Cervical epidural injections are similar in technique to lumbar epidural injections in some respects. The cervical spinous processes at C7 and T1 are oriented almost horizontally, as in the lumbar region. Of note, caution must be taken because the cervical ligamentum flavum is thinner in this region than at any other spinal level, and the width of the epidural space is only 3 to 4 mm. A catheter may be placed through a nonshearing needle to achieve the desired level under fluoroscopic guidance.

### Complications

The most frequent complication of a cervical epidural injection is subarachnoid penetration (wet tap) due to the thinner ligamentum flavum and the reduced width of the cervical epidural space. Cervical epidural injections should only be attempted by those physicians with a great deal of experience with lumbar epidural techniques, because the spinal cord lies in close proximity to the epidural space. These injections are normally completed with fluoroscopic guidance, as noted in Chapter 68. Injection of local anesthetics into the cervical epidural space can result in respiratory depression, particularly if the phrenic nerve roots are blocked (C3 to C5).

Infection or bleeding into the closed epidural space also can result in significant neurologic deficits, including quadriplegia. Any complaint of increasing pain or neurologic changes should be investigated immediately. Early recognition can prevent permanent injury.

## Suprascapular Nerve Block

### Indication

The suprascapular nerve blockade is useful in patients as a therapeutic procedure for pain in the shoulder region. This block is used as an adjuvant to physical therapy in patients with limited range of motion secondary to arthritic shoulder pain, shoulder-hand syndrome, and shoulder pain.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position. The spine of the scapula is divided by a line formed by the bisection of the scapular angle. The upper outer quadrant formed from the spine of the scapula and the vertical line bisecting the angle of the scapula is marked, and a point is marked 2 cm anteriorly along this line for needle insertion. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3-in. (8-cm), 23- to 25-gauge needle is inserted perpendicular to the skin and, using a nerve stimulator, advanced until needle placement is confirmed by movements of the supraspinatus and infraspinatus muscles. After negative aspiration, 5 mL of local anesthetic is injected (Fig. 67-5).

### Comments

The suprascapular nerve is a branch from the trunk of the brachial plexus, which enters the scapular region through the suprascapular notch on the cephalic border of the scapula. Confirmation of the block is determined when abduction of the arm is diminished over the first 15 degrees. If a nerve stimulator is not available, the same technique is used, with the needle advanced to the dorsal surface of the scapula. The needle is then walked along the edge of the scapula to the suprascapular notch.

### Complications

Intraneural injection may result in nerve damage. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be repositioned immediately. Hematoma and intravascular injection are possible, owing to the close proximity of the suprascapular vessels. Pneumothorax is possible if the needle is advanced beyond the scapula and into the pleura. Most pneumothoraces can be treated easily with administration of supplemental oxygen and close observation and, when necessary, needle aspiration of air. Only those pneumothoraces that result in significant dyspnea or those under tension require chest tube thoracotomy and vacuum drainage.

**FIGURE 67-5.** Suprascapular nerve block. Approach for suprascapular nerve injection and neural blockade. (From Murphy TM, Raj PP, Stanton-Hicks M. Techniques of nerve blocks: spinal nerves. In: Raj PP, ed. *Practical Management of Pain*. Chicago: Yearbook Medical; 1986:621, with permission.)

## Intercostal Nerve Block

### Indications

Intercostal blockade is used to treat pain from herpes zoster, rib fractures, and intercostal neuropathies. It is also used to diagnose unusual abdominal or chest wall pain.

### Techniques

After informed consent is obtained, the patient is placed in either the prone or lateral position. In the lateral position, the injection site is along the midaxillary line, which may result in incomplete blockade of the lateral cutaneous branch of the intercostal nerve. In the prone position, the injection site is along the angle of the rib posteriorly. The ribs to be injected are marked at the angle of the rib or along the midaxillary line. If the ribs are not easily palpated, an alternative injection

technique such as an epidural or root block may be considered. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and strict sterile technique is used throughout the procedure. The index finger of the nondominant hand is used to palpate the rib and identify the intercostal space. The tip of the finger is placed in the intercostal space and the skin slid over the superior rib. A  $\frac{5}{8}$ -in. (1.5-cm), 25-gauge needle is inserted directly over the rib until contact is made with the rib. The long axis of the needle and syringe should have a slight cephalad tilt and be perpendicular to the long axis of the rib. The needle is then moved to the inferior edge of the rib by walking (i.e., repeatedly slightly withdrawing) the needle in the subcutaneous tissue and allowing the skin to move back slowly to its original position. The needle should retain its slight cephalad tilt. As the needle slips off the inferior ridge of the rib, the tip is advanced about 3 mm and then aspirated. If aspiration is positive for blood or air, the needle should be repositioned; otherwise, 2 to 5 mL of local anesthetic is injected to block the intercostal nerve (Fig. 67-6).

### Comments

A new needle should be used for each nerve blocked. Intercostal blocks are a simple and effective method of providing analgesia for painful disorders of the chest and abdominal walls. Because of the wide distribution of intercostal nerve innervation, the intercostal nerves above and below the level of pain must be blocked to gain optimal pain relief.

### Complications

Intercostal blockade is often underused because of an exaggerated fear of pneumothorax. In actuality, less than 1% of all patients having an intercostal block develop a pneumothorax. Most can be easily treated with administration of supplemental oxygen and close observation and, when necessary, needle aspiration of air. Only those pneumothoraces that result in significant dyspnea or those under tension require chest tube thoracotomy and vacuum drainage. Local anesthetic toxicity can occur because of the rapid absorption after intercostal injection. Toxicity can easily be avoided by limiting the total amount injected to a known, safe level (see Table 67-4).

## Spinal Nerve Root Block

### Indications

Nerve root blockade is useful in diagnosing and treating pain present in a dermatomal distribution.

### Techniques

After informed consent is obtained, the patient is placed in the prone position, and a line perpendicular to the axis of the spine is drawn across the top of the spinous process. In the lumbar region, a line drawn along the inferior edges of the two transverse processes will intersect the spinous process of the same vertebra at its most cephalad point. In the thoracic region, this line can extend as much as two vertebral levels caudally,

particularly in the midthoracic region. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and strict sterile technique is used throughout the procedure. A 4-in. (10-cm), 22-gauge needle is inserted 3 to 5 cm laterally from the midline, which should overlie the transverse process. The needle is advanced perpendicular to the skin until contact is made with the transverse process. The depth is noted at this point. The needle is pulled back to skin level and redirected to pass below the transverse process. Appropriate response with a nerve stimulator or paresthesia indicates correct placement. After negative aspiration, 2 to 5 mL of local anesthetic is injected to block the spinal nerve root (Fig. 67-7).

### Comments

The technique of nerve root blockade is similar to that of the intercostal block. The transverse process serves as the depth marker for nerve roots. A sound knowledge of the relationship of the transverse process and the spinous process is necessary to locate precisely the selected nerve root. Any disorder that responds to intercostal blockade also should respond to selective nerve root blockade.

### Complications

Complications usually occur from injection of local anesthetic agents into areas adjacent to the paravertebral space such as the epidural or subarachnoid space. Puncture of retroperitoneal organs and bleed also can occur if care is not taken to consider the anatomy fully.

## Celiac Plexus Block

### Indications

Celiac plexus blockade is useful for diagnosing and treating pain of sympathetic origin. This includes pain involving the viscera, abdomen, and pelvis, secondary to cancer, complex regional pain syndrome, and vasospastic disorders.

### Techniques

After informed consent is obtained, the patient is placed in the prone position with a pillow under the abdomen. The inferior edge of the spinous process of the first lumbar vertebra and the lower border of each 12th rib at 7 cm from the spinous process of the first lumbar vertebra is identified and marked. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 6-in. (15-cm), 22-gauge needle is inserted at the mark on the 12th rib toward the spinous process of L1 at 60 degrees from perpendicular. The needle is advanced until it contacts the lateral side of the L1 vertebra. The depth is noted at this point. The needle is pulled back to a subcutaneous level and reinserted at 45 degrees toward the spinous process of L1 and slightly cephalad until it slips off the edge of the vertebra. This is about 2 to 3 cm deeper than the original depth. After negative aspiration, 20 mL of local anesthetic is injected (Fig. 67-8).

**FIGURE 67-6.** Intercostal nerve block. Approach for intercostal nerve injection and neural blockade with injection sites marked at the angle of the rib. **A:** The tip of the finger is placed in the intercostal space and the slid (arrow) slid over the superior rib. **B:** The needle is inserted directly over the rib until contact is made. **C:** The needle is walked (arrow) to the inferior edge of the rib while maintaining a slight cephalad tilt. **D:** As the needle slips off the inferior edge of the rib, advance the needle approximately 3 mm (arrow), where it is adjacent to the intercostal nerve. (From Thompson GE, Moore DC. Celiac plexus, intercostal, and minor peripheral blockage. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:459, with permission.)

**FIGURE 67-7.** Spinal nerve root block. **A:** Fluoroscopic view for L5 nerve root block (arrow). **B:** Approach for spinal nerve root injection and neural blockade. (From Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:420, with permission.)

### Comments

This technique is commonly used for differential diagnosis and is the preferred treatment of sympathetic mediated pain involving the viscera and pelvis. The celiac plexus is located in the prevertebral region at the level of the L1 vertebral body. It is formed by the right and left celiacs, superior mesenteric, and aorticorenal ganglia. Autonomic mediated pain does not usually correspond to segmental or peripheral nerve distribution. Lateral and anteroposterior fluoroscopic views are recommended to ensure that the needle is properly positioned. It is recommended that intravenous access be available before the block in the event of hypotension from sympathectomy or toxicity from intravascular injection. It is necessary to perform this procedure bilaterally for a complete celiac plexus block. Rarely are ablative nerve procedures (neurolysis) required in the management of sympathetic mediated pain.

### Complications

These injections are normally completed with fluoroscopic guidance, as noted in Chapter 68. Performance of this procedure out of a fully monitored environment is not recommended.

Resuscitation equipment and personnel must be readily available. Although appearing technically simple, this block has multiple hazards, owing to the proximity of the aorta, kidney, pancreas, diaphragm, thoracic duct, and other vascular structures. Intraarterial or intradural injection of local anesthetic may result in death, seizure, respiratory arrest, cardiac arrest, cerebral damage with multiple sequelae, and other lesser complications. The risk for intravascular injection may be reduced if a test dose is given, the total dose is injected incrementally, and aspiration is performed before each injection.

## Lumbar Epidural Steroid Injection

### Indications

ESI is most effective for lumbosacral radiculopathy associated with intervertebral disc herniation, bulging, or degeneration. The main criterion for success is the presence of nerve root inflammation that can be relieved by the steroid. ESI also has been used to treat pain from degenerative joint disease, scoliosis, spondylolysis, spondylolisthesis, postlaminectomy syndrome, facet abnormalities, herpes zoster, and postherpetic neuralgia.

**FIGURE 67-8.** Celiac plexus block. Approach for celiac plexus injection and neural blockade. (From Raj PP, Pai U, Rawal N. Techniques of regional anesthesia in adults. In: Raj PP, ed. *Clinical Practice of Regional Anesthesia*. New York, NY: Churchill-Livingstone; 1991:496, with permission.)

### Techniques

After informed consent is obtained, the patient is placed prone, lateral decubitus, or sitting with the back, hips, and knees flexed. The injection should be performed as close as possible to the bony level of the nerve root irritation. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. Local skin anesthesia is provided with 1% to 2% lidocaine. A Tuohy epidural needle is then advanced between the spinous processes in a midline (or paramedian) approach until the needle is well seated in the posterior ligaments. The stylet is then removed and a loss-of-resistance syringe is attached to the hub of the needle. Two to 3 mL of normal saline should be in the syringe. The needle is slowly advanced 1 to 2 mm at a time, with constant checking for loss of resistance by tapping on the plunger of the syringe, or advanced slowly and continuously with light pressure on the plunger. Once a distinct loss of resistance is obtained, the needle is halted, and an attempt is made to aspirate blood or CSF. After negative aspiration, either 40 to 80 mg of methylprednisolone acetate or 6 mg mixture of betamethasone sodium phosphate and betamethasone acetate is injected. The steroids can be injected as is or diluted in 5 to 10 mL of preservative-free normal saline. If multiple levels are involved, dilution will ensure better spread of the steroid. The needle should be flushed with normal saline and the stylet replaced before it is removed from the skin to avoid tracking steroid to the skin. If blood is obtained on aspiration, the needle should be repositioned. If CSF is obtained on aspiration, the procedure can be continued; however, a spinal headache may result from dural puncture, and intrathecal injection is a possibility at this location (Fig. 67-9). The needle can be reintroduced at an adjacent level.

### Comments

A complete evaluation of the pain should be undertaken before ESI to rule out serious neurologic dysfunction or malignancy. Local infection, sepsis, coagulation abnormalities, and patient refusal are contraindications to ESI. Success is higher if the patient has had no previous back surgeries and the pain has been present for less than 6 to 12 months. Methylprednisolone acetate is best used for localized nerve root irritation. Triamcinolone diacetate is water soluble and results in optimal outcome in generalized nerve root irritation such as arachnoiditis.

The paraspinal (paramedian) approach may be used if difficulty is encountered with the midline approach. A Tuohy epidural needle is inserted alongside the caudal edge of the inferior spinous process to the bony level of nerve root irritation. The needle is inserted with a 45-degree angulation to the long axis of the spine below and a 10-degree offset from midline and then advanced between the spinous processes until it is well seated in the posterior ligaments.

### Complications

Inadvertent dural puncture may result in a postdural puncture headache. Risk of dural puncture is increased at sites of prior laminectomy. Intrathecal injection of steroid may result in aseptic meningitis, adhesive arachnoiditis, or conus medullaris syndrome. Each milliliter of methylprednisolone acetate contains about 30 mg of polyethylene glycol, which has been associated with nerve damage in experimental models (35). Epidural steroids can suppress plasma cortisol levels for about 3 to 5 weeks. Iatrogenic Cushing's syndrome, fluid retention, and elevated serum glucose levels also can occur (36).

Infection or bleeding into the closed epidural space also can result in significant neurologic deficits, including quadriplegia. Any complaint of increasing pain or neurologic changes

**FIGURE 67-9.** Lumbar epidural steroid injection. Approach for lumbar epidural steroid injection. **A:** Midline. Note that insertion is closer to the superior spinous process and with a slight upward angulation. **B:** Paraspinous (paramedian). Note insertion alongside caudal edge of “inferior” spinous process with 45-degree angulation to long axis of spine below. (From Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:293, with permission.)

should be investigated immediately. Early recognition can prevent permanent injury.

## Lumbar Sympathetic Block

### Indications

Lumbar sympathetic blockade is useful for diagnosing and treating pain of sympathetic origin. This includes pain involving the pelvis and lower extremity, secondary to complex regional pain syndrome, vasospastic disorders, and phantom pain.

### Techniques

The spinous process of the second or third lumbar vertebra is palpated, and a point is marked 4 cm lateral to the middle of the spinous process. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 4-in. (10-cm), 22-gauge needle is inserted and advanced cephalad until contact is made with the transverse process. The needle is pulled back to skin level and redirected to pass between the transverse processes and alongside the anterolateral aspect of the vertebral body. After negative aspiration, 20 mL of local anesthetic is injected (Fig. 67-10).

### Comments

This technique is commonly used for differential diagnosis and is the preferred treatment of sympathetic mediated pain involving the lower extremity. The lumbar sympathetic ganglia are located along the anterior lateral surface of the lumbar vertebral bodies and anteromedial to the psoas muscle. Autonomic mediated pain does not usually correspond to segmental or

peripheral nerve distribution. Lateral and anteroposterior fluoroscopic views are recommended to ensure that the needle is properly positioned. It is recommended that intravenous access be available before the block in the event of local anesthetic toxicity and resulting seizure activity. Rarely are ablative nerve procedures (neurolysis) required in the management of sympathetic mediated pain.

**FIGURE 67-10.** Lumbar sympathetic approach. Fluoroscopic approach for lumbar sympathetic injection and neural blockade (arrow).

### Complications

These injections are normally completed with fluoroscopic guidance, as noted in Chapter 68. Performance of this procedure outside of a fully monitored environment is not recommended. Resuscitation equipment and personnel must be readily available. Although appearing technically simple, this block has multiple hazards, owing to the proximity to the aorta, inferior vena cava, kidney, pancreas, and intestines. Intraarterial or intradural injection of local anesthetic may result in death, seizure, respiratory arrest, cardiac arrest, cerebral damage with multiple sequelae, and other lesser complications. The risk for intravascular injection may be reduced if a test dose is given, the total dose is injected incrementally, and aspiration is performed before each injection. Significant hypotension from the sympathetic block is possible but usually does not occur with unilateral block.

### Caudal Injection

#### Indications

The caudal approach to the epidural space is used to treat pain in the lower back and pelvis.

#### Techniques

After informed consent is obtained, the patient may be placed in a variety of positions, with patient comfort probably as

the prime concern. The preferred position is the lateral Sims' position with the left side down for right-handed clinicians. With the upper leg flexed, the buttocks are separated, allowing easy access to the sacral-coccygeal junction. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. The midline is identified by palpating the tip of the coccyx with a finger and moving cephalad about 4 to 5 cm in an adult, until the fingertip lies over the sacral hiatus with the sacral cornua palpable on each side. The palpating hand is kept in position, and a 2-in. (5-cm), 18-gauge short, beveled needle is inserted. The initial angle of insertion is about 120 degrees to the coccyx. A "pop" is felt as the sacrococcygeal ligament is penetrated. The needle is then depressed to align with the long axis of the canal and inserted 1 cm. Once the caudal space has been entered, epidural positioning is confirmed by negative aspiration blood or CSF, then 40 to 80 mg of methylprednisolone acetate or 6 mg mixture of betamethasone sodium phosphate and acetate is injected. The steroids can be injected as is or diluted in 5 to 10 mL of preservative-free normal saline (Fig. 67-11).

#### Comments

Epiduroscopy, a technique used to visualize the lumbar epidural space, depends on this approach because the fiberoptic catheter

**FIGURE 67-11.** Caudal injection. **A:** Landmarks and approach for needle insertion. **B:** Needle insertion through sacral-coccygeal membrane for injection. (From Willis RJ. Caudal epidural blockade. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:333, with permission.)

cannot tolerate bending. Advantages of this approach include minimal risk for inadvertent dural puncture. Continuous catheter techniques can be used, but maintenance of site cleanliness is more difficult when compared with the lumbar approach to the epidural space. A Tuohy needle is not used for catheter placement because it will direct the catheter against the wall of the caudal canal and make catheter advancement difficult. Caudal epidurals and epidural lysis of adhesions can be performed via radiopaque catheter through a nonshearing needle under fluoroscopic guidance. Betamethasone sodium phosphate and acetate mixture is best used for localized nerve root irritation. Triamcinolone diacetate is water soluble and results in optimal outcome in generalized nerve root irritation such as arachnoiditis.

### Complications

Improper needle placement can result in inadequate or absent block. This is due to variability in anatomy and inexperience. Rapid injection of large volumes of fluid is not recommended because this may result in large increases in CSF pressures, with the risk for cerebral hemorrhage, visual disturbances, headache, or compromised spinal cord blood flow. Pain at the injection site is a common complaint. Urinary retention can result from local anesthetic injection and should last only as long as the block.

## Lateral Femoral Cutaneous Nerve Block

### Indications

Lateral femoral cutaneous nerve blockade is useful for diagnosing and treating pain in the lateral thigh, thought to be from irritation of this nerve.

### Techniques

After informed consent is obtained, the patient is placed in a supine position, and the anterosuperior iliac spine is palpated. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 23-gauge needle is inserted 1 cm medially and below the anterosuperior iliac spine. The needle is advanced deeply into the fascia lata toward the shelving of the iliac crest. After negative aspiration, 5 mL of local anesthetic is injected in a fanwise manner (Fig. 67-12).

This nerve can be blocked through an alternative approach by directing the needle superiorly beneath the inguinal ligament into the fascial compartment containing the nerve above the level of the inguinal ligament. This fascial compartment can be identified by directing a short, beveled needle medially to the anterosuperior iliac spine and advancing through the external oblique aponeurosis, the internal oblique muscle, and the fascia iliaca. The short, beveled needle allows the physician to feel a distinct loss of resistance or characteristic pop as the two fascial layers are penetrated. After negative aspiration, 5 mL of local anesthetic is injected to block the lateral femoral cutaneous nerve.

**FIGURE 67-12.** Lateral femoral cutaneous nerve block. Approach for lateral femoral cutaneous nerve injection and neural blockade. (From Raj PP, Pai U, Rawal N. Techniques of regional anesthesia in adults. In: Raj PP, ed. *Clinical Practice of Regional Anesthesia*. New York, NY: Churchill-Livingstone; 1991:384, with permission.)

### Comments

The lateral femoral cutaneous nerve emerges along the lateral border of the psoas muscle below the ilioinguinal nerve. It runs obliquely under the iliac fascia across the iliacus muscle and enters the thigh by passing posteriorly to the inguinal ligament, just medial to the anterosuperior iliac spine. It provides cutaneous innervation to the lateral aspect of the thigh to the knee. A large area over the lateral aspect of the thigh can be easily blocked with this technique.

### Complications

The lateral femoral cutaneous nerve block has no significant complications, with the rare exception of a dysesthesia if the nerve is injured during the injection. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be immediately repositioned. It is possible to block the femoral nerve inadvertently when large amounts of local anesthetic is injected, resulting in a temporary weakness of knee extension and impaired ambulation. This occurs secondary to the medial spread of local anesthetic beneath the fascia iliaca.

## Femoral Nerve Block

### Indications

Femoral nerve blockade is useful in conjunction with other lower extremity blocks in treating complex regional pain

syndrome and as an aid to decrease knee and ankle pain during physical therapy.

### Techniques

After informed consent is obtained, the patient is placed in the supine position, and the femoral artery is located. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. The femoral artery is palpated below the inguinal ligament. A 1½-in. (4-cm), 22-gauge needle is inserted 1 to 2 cm below the inguinal ligament and lateral to the femoral artery. The needle is advanced in a lateral and posterior direction just distal to the inguinal ligament. A characteristic pop, when using a short, beveled needle, can be used to identify penetration of the fascia lata and the fascia iliaca, remembering that the femoral nerve lies deeper than both. When a nerve stimulator is used, contraction of the quadriceps muscle confirms correct placement of the needle. After negative aspiration, 10 mL of local anesthetic is injected to block the femoral nerve (Fig. 67-13).

### Comments

At the level of the inguinal ligament, the femoral nerve lies anterior to the iliopsoas muscle and slightly lateral to the femoral artery. It does not lie within the femoral sheath. The nerve lies underneath the fascia lata and fascia iliaca within its own sheath. At the level

**FIGURE 67-13.** Femoral nerve block. Approach for femoral nerve injection and neural blockade. (From Bridenbaugh PO. The lower extremity: somatic block. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:376, with permission.)

of the inguinal ligament, the femoral nerve divides into anterior (superficial) and posterior (deep) bundles. The anterior bundle provides cutaneous innervation of the skin overlying the anterior surface of the thigh as well as providing motor innervation to the sartorius muscle. The posterior bundle provides innervation to the quadriceps muscles and the knee joint. It also gives off the saphenous nerve, which supplies cutaneous innervation to the medial aspect of the calf to the level of the medial malleolus. A catheter also can be placed within the femoral nerve sheath for continuous infusion of local anesthetics.

It is important to remember that the upper portion of the anterior thigh is innervated by the ilioinguinal and genitofemoral nerves and is not blocked when performing a femoral nerve block.

### Complications

Significant complications associated with femoral nerve blockade are uncommon. Dysesthesia may result if the nerve is injured during the injection. Hematoma at the site is a possibility but is usually not clinically significant. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma. The presence of a femoral artery vascular graft is a relative contraindication to femoral nerve blockade.

### Obturator Nerve Block

#### Indications

Obturator nerve blockade is extremely useful as a diagnostic, prognostic, or therapeutic procedure in patients with adductor spasm that interferes with rehabilitation or personal hygiene.

#### Techniques

After informed consent is obtained, the patient is placed in the supine position with the leg to be blocked placed in slight abduction. It is not necessary to shave the pubic area. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3-in. (8-cm), 22-gauge needle is inserted perpendicular to the skin at a point 1.5 cm lateral and inferior to the pubic tubercle. The needle is advanced until the inferior ramus of the pubis is contacted. The needle depth at which the bone is contacted should be noted. The needle is withdrawn to skin level and redirected in a lateral and slightly superior direction, parallel to the superior ramus of the pubis. The needle is advanced 2 to 3 cm beyond the previously noted depth until a paresthesia is elicited. A nerve stimulator makes it relatively easy to identify the obturator nerve by adductor muscle contraction. After negative aspiration for blood, 10 mL of local anesthetic is injected to block the obturator nerve. This traditional approach was first described by Labat (37) (Fig. 67-14).

Using the above techniques, Wassef has described an alternative approach using the femoral artery and adductor longus tendon as landmarks (38). A mark is made on the skin 1 to 2 cm medial to the femoral artery just below the inguinal ligament. This mark is used to indicate the direction of the

**FIGURE 67-14.** Obturator nerve block. Approach for obturator nerve injection and neural blockade. (From Bridenbaugh PO. The lower extremity: somatic block. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:386, with permission.)

needle toward the obturator canal. The adductor longus tendon is then identified near its insertion site at the pubis. A 3-in. (8-cm), 22-gauge insulated needle is introduced behind the adductor longus tendon and directed laterally, with a slight posterior and superior inclination toward the skin mark. The needle is advanced until adductor muscle contraction is elicited with a nerve stimulator (39).

### Comments

The obturator nerve is formed by the union of the ventral branches of the anterior primary rami of L2, L3, and L4 within the substance of the psoas muscle. It emerges from the medial border of the psoas muscle at the brim of the pelvis. The nerve runs caudad and anteriorly along the lateral wall of the pelvis, along the obturator vessels to the obturator foramen. There it enters the thigh, supplying the adductor muscles and providing innervation to the hip and knee joints.

As the nerve passes through the obturator canal, it divides into anterior and posterior branches. The anterior branch supplies the hip joint, the anterior adductor muscles, and cutaneous branches to the medial aspect of the thigh. The cutaneous innervation of the obturator nerve can be extremely variable and can be nonexistent in some people. The posterior branch supplies the deep adductor muscles and frequently sends a branch to the knee joint.

This procedure is often performed on rehabilitation patients with spasticity or contractures that result in positioning difficulty. Confirmation of a successful obturator nerve block is demonstrated by paresis of the adductor muscles because the cutaneous contribution of the obturator nerve is inconsistent. An alternative to this procedure is selective root blockade at levels L2, L3, and L4 using a nerve stimulator to establish muscle innervation.

### Complications

Hematoma and intravascular injection are possible due to the close proximity of the obturator vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

## Sciatic Nerve Block

### Indications

Sciatic nerve blockade is typically used to treat painful conditions of the lower leg such as complex regional pain syndrome and to facilitate physical therapy by decreasing pain in the lower extremity.

### Techniques

A regional block of the sciatic nerve can be achieved anywhere along the course of the nerve. Most of the approaches have been developed mainly to avoid positioning problems that may be present in trauma patients or elderly people. The nerve can be blocked at the sciatic notch, at the level of the ischial tuberosity, greater trochanter, or superior aspect of the popliteal fossa.

### Classic Approach

The classic technique described by Labat (37) blocks the nerve at the level of the greater sciatic notch, using the piriformis muscle as a landmark. After informed consent is obtained, the patient is placed in the lateral Sims' position with the side to be blocked uppermost. The upper knee is flexed, and the patient's back is rotated slightly forward. Some patients may find this position uncomfortable, particularly those with orthopedic problems.

The landmarks are the cephalad portion of the greater trochanter and the posterosuperior iliac spine. A line is drawn connecting these two points, corresponding to the superior border of the piriformis muscle and the upper border of the sciatic notch. A perpendicular line is drawn distally from the midpoint of the first line. The point of injection is 3 to 5 cm distal on the perpendicular line. Verification of the insertion point can be made by drawing a third line connecting the cephalad portion of the greater trochanter and the sacrococcygeal joint. This third line is used to compensate for the height of the patient. The intersection of lines 2 and 3 is the point of needle insertion (Fig. 67-15).

The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 4- to 5-in. (10- to 12-cm), 22-gauge spinal needle is

**FIGURE 67-15.** Sciatic nerve block: classic approach. Classic approach for sciatic nerve injection and neural blockade. (From Bridenbaugh PO. The lower extremity: somatic block. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:379, with permission.)

introduced at right angles to the skin and advanced to a depth of 6 to 10 cm until a paresthesia is reported in the distribution of the sciatic nerve, preferably involving the foot. If periosteum is contacted, the needle is then redirected medially or superiorly. Touching the periosteum may produce a local paresthesia, which could be mistaken for a true sciatic nerve paresthesia. A nerve stimulator is extremely helpful in locating the nerve (39).

Doppler ultrasound also can be used to locate the dominant arterial structure within the sciatic notch (40). The needle is then advanced in the same orientation as the probe until a paresthesia is obtained. Successful blockade has been reported after one or two attempts in 70% of patients. After negative aspiration for blood, 20 to 30 mL of local anesthetic is injected to block the sciatic nerve.

A continuous sciatic nerve block can be performed by using a standard 16-gauge intravenous infusion cannula attached to a nerve stimulator. After obtaining muscle contraction in the lower leg, preferably dorsal or plantar flexion of the foot, an epidural catheter is advanced about 6 cm into the neurovascular space. Continuous infusion of a local anesthetic using an infusion pump can then be used to provide continuous analgesia (41). With the classic approach, both the posterior femoral cutaneous and pudendal nerves are usually blocked with the sciatic nerve.

### Posterior Approach

An alternate approach may be used, with the patient positioned as above or prone. The ischial tuberosity and the greater trochanter are identified and a line drawn connecting these two

points. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3- to 4-in. (8- to 10-cm), 22-gauge spinal needle is inserted at the midpoint of the line until a paresthesia is elicited in the lower leg. After negative aspiration, 20 to 30 mL of local anesthetic is injected to block the sural nerve. The posterior femoral cutaneous nerve is often blocked at this level, but the pudendal nerve is frequently spared.

### Anterior Approach

The anterior approach allows the sciatic nerve to be blocked without moving the patient, enabling the patient to remain in the supine position (37,42). This approach is especially helpful in trauma patients with a painful leg, but it is quite painful, and sedation is often necessary. The nerve is very deep at this point and can be difficult to locate. In adults, the sciatic neurovascular compartment is usually 4.5 to 6 cm below the surface of the femur. In children, however, the distance varies according to age and size of the child (43). The use of a nerve stimulator is advised in identifying the nerve. The posterior cutaneous nerve of the thigh may not be blocked with this approach, as tourniquet pain could result if a thigh tourniquet is applied (Fig. 67-16).

The patient is placed in the supine position with the leg in a neutral position. The anterosuperior iliac spine and the pubic tubercle are identified and marked. A line is then drawn connecting these two points, overlying the inguinal ligament, and trisected into equal parts. A perpendicular line is drawn distally from the junction of the medial and middle thirds.

**FIGURE 67-16.** Sciatic nerve block: anterior approach. Anterior approach for sciatic nerve injection and neural blockade. Cross section of the leg at the level of the lesser trochanter to show the relationship between the sciatic nerve and femur and the fascia separating it from the adductor magnus. (From Bridenbaugh PO. The lower extremity: somatic block. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:382, with permission.)

A third line is drawn parallel to the first, starting from the cephalad aspect of the greater trochanter. The point of intersection of this third line and the perpendicular line is the insertion point of the needle.

The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 6-in. (15-cm), 22-gauge spinal needle is inserted and directed slightly laterally from a plane perpendicular to the skin. The needle is advanced until periosteum is contacted (usually the lesser trochanter). The needle is partially withdrawn and redirected medially and

posteriorly to pass about 5 cm beyond the femur until a paresthesia is elicited. After negative aspiration, 20 to 25 mL of local anesthetic agent is injected to block the sural nerve.

### Lateral Approach

The lateral approach, initially described by Ichiyanaghi (44), was found to be very difficult and never became popular. A new lateral approach described by Guardini et al. (45) is easier. It blocks the sciatic nerve just posterior to the quadratus femoris muscle in the subgluteal space.

The greater trochanter is identified, and the patient is prepared in a standard sterile fashion. A 5- to 6-in. (12- to 15-cm), 22-gauge spinal needle is advanced 3 cm distal to the maximum lateral prominence of the trochanter, close to its posterior margin. The needle is inserted until the periosteum is contacted. The needle is then partially withdrawn and redirected posteriorly and medially to slide beneath the femoral shaft until a paresthesia, or contraction of the calf or the anterior compartment muscles, occurs with the use of a nerve stimulator. After negative aspiration, 20 to 30 mL of local anesthetic is injected to block the sural nerve.

The main advantage of this technique is that the patient can remain in the supine position and the leg need not be manipulated. When using a nerve stimulator, it is important to make sure that the muscle contractions occur in the calf muscles or in the muscles of the anterior compartment. It is possible with this technique to stimulate inadvertently the nerve branch supplying the two heads of the biceps femoris muscle, producing thigh muscle contraction and misplacement of the local anesthetic.

### Comments

The sciatic nerve is the largest in the body. It arises from both the lumbar and sacral plexuses. Anatomically, the sciatic nerve consists of two major nerve trunks: the tibial and common peroneal components. The tibial nerve is derived from the anterior rami of L4 to S3 nerve roots. The common peroneal nerve is derived from the dorsal branches of the anterior rami of the same roots. It leaves the pelvis along with the posterior cutaneous nerve of the thigh through the sciatic foramen beneath the inferior margin of the piriformis muscle. It passes halfway between the greater trochanter and the ischial tuberosity. It becomes superficial at the inferior border of the gluteus maximus muscle and travels down the posterior aspect of the thigh. At the superior aspect of the popliteal fossa, the sciatic nerve physically separates into the tibial and common peroneal nerves.

In the past, the sciatic nerve block was considered unreliable, technically difficult, and uncomfortable for the patient. Sedation was often required, and this interfered with the patient's ability to provide accurate verbal feedback. This was especially the case if a paresthesia was used to identify the nerve. Reported rates of success ranged between 33% and 95% using various techniques. Today's insulated needles and nerve stimulators have made it easier to perform this block safely in sedated or even anesthetized patients with a higher rate of success.

### Complications

Although the sciatic nerve is composed of mostly somatic nerves, it has a sympathetic component. The resulting sympathetic block may allow some mild venous pooling, but this is usually insufficient to cause clinically significant hypotension. Residual dysesthesias have been reported but usually improve in 1 to 3 days. This may be the result of nerve injury from the use of long beveled needles. Using short beveled needles for regional blocks may decrease the incidence of nerve injury.

## NERVE BLOCKS AT THE KNEE

Nerve blockade at the knee is primarily used to treat pain disorders in specific nerve distributions. Diagnostic tibial nerve blocks also can be helpful in evaluating patients with spastic hemiparesis or myotonic disorders (46). Many early textbooks of regional blockade discouraged individual nerve blocks at the knee because they were thought to be difficult to perform and there was a possibility of a postanesthetic neuritis (47). Recently, studies have shown these nerve blocks can be safely and successfully performed at the knee, even in children (48,49).

The common peroneal and tibial nerves are extensions of the sciatic nerve. The sciatic nerve bifurcates at the superior aspect of the popliteal fossa, bordered by the biceps femoris muscle laterally and the semimembranosus and semitendinosus muscles medially. The two heads of the gastrocnemius muscle border the lower half of the popliteal fossa. Techniques have been described in which the tibial and common peroneal nerves are blocked with one injection, but it is possible to miss one of the branches (50). Identifying the two nerves separately and performing individual nerve blocks increases the likelihood of success.

### Tibial Nerve Block

#### Indications

Tibial nerve blockade is useful as a diagnostic, prognostic, or therapeutic procedure in painful disorders involving the ankle and foot.

#### Techniques

After informed consent is obtained, the patient is placed in the prone position. The knee is flexed to allow palpation of the superior popliteal fossa borders and identification of the skin crease behind the knee joint. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (3- to 4-cm), 21- to 23-gauge needle is inserted just above the crease line in the middle of the popliteal fossa. A nerve stimulator is used to identify the tibial nerve by eliciting plantar flexion of the foot. The average depth from skin to nerve in adults is 1.5 to 2 cm. After negative aspiration, 5 mL of local anesthetic is injected to block the tibial nerve (Fig. 67-17).

#### Comments

The tibial nerve is the larger of the two branches of the sciatic nerve and supplies motor innervation to the flexor muscles at

the back of the knee joint and calf. The cutaneous innervation supplies the skin overlying the popliteal fossa and down the back of the leg to the ankle. It travels through the center of the popliteal fossa as it proceeds distally down the leg.

### Complications

Hematoma and intravascular injection are possible, owing to the close proximity of the popliteal vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

### Common Peroneal Nerve Block

#### Indications

Common peroneal nerve blockade is useful as a diagnostic, prognostic, or therapeutic procedure in painful disorders involving the ankle and foot.

#### Techniques

After informed consent is obtained, the patient is placed in the supine or lateral position. The common peroneal nerve can be easily palpated as it crosses the neck of the fibula. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 25-gauge needle is inserted next to the nerve and advanced to contact the periosteum, with care being taken to avoid an intraneural injection. A sudden, intense pain on injection suggests intraneural injection. If this occurs, the needle should be repositioned before proceeding. A nerve stimulator may be used to identify the nerve by eliciting contraction of the anterior compartment muscles. The needle is withdrawn slightly, and after negative aspiration, 5 mL of local anesthetic is injected to block the peroneal nerve (see Fig. 67-17).

#### Comments

The common peroneal nerve is about half the size of the tibial nerve and contains articular branches to the knee joint. It provides motor innervation to the extensor muscles of the foot and cutaneous nerves to the lateral aspect of the leg, heel, and ankle. It separates from the tibial nerve at the superior aspect of the popliteal fossa and courses laterally around the fibular head where it divides into the deep and superficial peroneal nerves.

### Complications

Complications from the common peroneal nerve block are rare, especially when care is taken to avoid an intraneural injection. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be immediately repositioned.

### Saphenous Nerve Block

#### Indications

Saphenous nerve blockade is useful as a diagnostic, prognostic, or therapeutic procedure in painful disorders involving the knee, ankle, and foot.

**FIGURE 67-17.** Tibial and common peroneal nerve block at the knee. Approach for tibial and common peroneal nerve injection and neural blockade at the knee. Tibial and common peroneal (lateral popliteal) nerve. (From Bridenbaugh PO. The lower extremity: somatic block. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:387, with permission.)

### Techniques

After informed consent is obtained, the patient is placed in the supine or lateral position. The saphenous nerve is located at the medial surface of the medial condyle of the femur at about the same level as the apex of the patella. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 25-gauge needle is inserted perpendicular to the skin just below the medial surface of the tibial condyle. After negative aspiration, 5 to 10 mL of local anesthetic is injected subcutaneously to block the saphenous nerve (Fig. 67-18).

### Comments

The saphenous nerve is the terminal branch of the femoral nerve. It provides cutaneous innervation to the skin overlying the medial, anteromedial, and posteromedial aspects of the leg from just above the knee to the level of the medial malleolus and, in some patients, to the medial aspect at the base of the great toe. There is no motor component.

### Complications

The saphenous vein may accompany the saphenous nerve, and the patient should be made aware of the possibility of a hematoma from venous puncture. Other complications from the saphenous nerve block are rare, especially when care is taken to avoid an intraneural injection. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be repositioned immediately.

## NERVE BLOCKS AT THE ANKLE

Nerve blockade at the ankle is primarily used to treat pain disorders in specific nerve distributions. There are five terminal branches of the tibial, common peroneal, and femoral nerves that supply the ankle and foot: posterior tibial, sural, superficial peroneal, deep peroneal, and saphenous nerves. These nerves are relatively easy to block at the level of the ankle.

In general, five nerve blocks form a ring of infiltration around the ankle at the level of the malleolus. It is important to

**FIGURE 67-18.** Saphenous nerve block at the knee. Approach for saphenous injection and neural blockade at the knee. (From Raj PP, Pai U, Rawal N. Techniques of regional anesthesia in adults. In: Raj PP, ed. *Clinical Practice of Regional Anesthesia*. New York, NY: Churchill-Livingstone; 1991:321, with permission.)

remember that large volumes of local anesthetic, especially those containing epinephrine, may cause vascular occlusion. Otherwise, neural blockade at the ankle is safe and highly successful.

## Tibial Nerve Block

### Indications

Tibial nerve blockade is used to treat pain disorders in the tibial nerve distribution of the foot.

### Techniques

After informed consent is obtained, the patient is placed in the prone position with the foot supported by a pillow. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A skin wheal is raised along the medial aspect of the Achilles tendon at the level of the superior border of the medial malleolus. A 1-in. (2.5-cm), 25-gauge needle is advanced through the wheal toward the posterior aspect of the tibia, behind the posterior tibial artery. If a paresthesia is elicited after negative aspiration, 3 to 5 mL of local anesthetic is injected after negative aspiration. If a paresthesia is not elicited, the needle is advanced until the tibial periosteum is contacted. The needle is withdrawn 0.5 cm, and after negative aspiration, 5 to 7 mL of local anesthetic is injected to block the posterior tibial nerve. A nerve stimulator may be used to identify the posterior tibial nerve by eliciting contraction of muscles in the sole of the foot (Fig. 67-19).

### Comments

The posterior tibial nerve is located along the medial aspect of the Achilles tendon, lying just behind the posterior tibial artery. The nerve gives off a medial calcaneal branch to the medial aspect of the heel, then divides behind the medial malleolus into the medial and lateral plantar nerves. The medial

plantar nerve supplies the medial two thirds of the sole of the foot as well as the plantar portion of the medial three and one-half toes. The lateral plantar nerve supplies the lateral one third of the sole and the plantar portion of the lateral one and one-half toes.

### Complications

Intraneural injection may result in nerve damage. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be repositioned immediately. Hematoma and intravascular injection are possible due to the close proximity of the posterior tibial vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

## Sural Nerve Block

### Indications

Sural nerve blockade is used to diagnose and treat pain disorders in the sural nerve distribution.

### Techniques

After informed consent is obtained, the patient is placed in a prone position with the foot supported by a pillow. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A skin wheal is raised lateral to the Achilles tendon at the level of the lateral malleolus. A 1-in. (2.5-cm), 25-gauge needle is inserted to a depth of 1 cm, directed toward the lateral border of the fibula. If a paresthesia is elicited, 2 to 3 mL of a local anesthetic is injected after negative aspiration. If a paresthesia cannot be elicited, after negative aspiration, 3 to 5 mL of local anesthetic is injected subcutaneously in a fan distribution from the lateral border of the Achilles tendon to the lateral border of the fibula to block the sural nerve (see Fig. 67-19).

**FIGURE 67-19.** Nerve blocks at the ankle. Approach for nerve injection and neural blockade at the ankle. (From Bridenbaugh PO. The lower extremity: somatic block. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:388, with permission.)

### Comments

The sural nerve is a cutaneous nerve that contains fibers from both the tibial and common peroneal nerves. It lies subcutaneous somewhat distally to the middle of the leg and travels with the short saphenous vein behind and below the lateral malleolus. It supplies the posterolateral surface of the leg, the lateral side of the foot, and the lateral aspect of the fifth toe.

### Complications

Intraneural injection may result in nerve damage. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be immediately repositioned. Hematoma and intravascular injection are possible, owing to the close proximity of the sural vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

## Superficial Peroneal Nerve Block

### Indications

Superficial peroneal nerve blockade is used to diagnose and treat pain disorders of the superficial peroneal nerve distribution in the foot.

### Techniques

After informed consent is obtained, the patient is placed in a supine position with the foot elevated on a pillow. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 25-gauge needle is inserted just laterally to the anterior border of the tibia at the proximal level of the lateral malleolus. The needle is carefully advanced to the superior aspect of the lateral malleolus. After negative aspiration, 5 mL of local anesthetic is injected over the course of the needle to block all the branches of the superficial peroneal nerve (see Fig. 67-19).

### Comments

The superficial peroneal nerve exits the deep fascia of the leg at the anterior aspect of the distal two thirds of the leg. From that point, the superficial peroneal nerve runs subcutaneously to supply the dorsum of the foot and toes, with the exception of the contiguous surfaces of the great and second toes.

### Complications

Complications are rare with the superficial peroneal nerve block.

## Deep Peroneal Nerve Block

### Indications

Deep peroneal nerve blockade is used to diagnose and treat pain disorders in the deep peroneal nerve distribution of the foot.

### Techniques

After informed consent is obtained, the patient is placed in a supine position with the foot elevated on a pillow. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 25-gauge needle is inserted between the extensor hallucis longus tendon and the anterior tibial tendon, just superior to the level of the malleoli. The extensor hallucis longus tendon can easily be identified by having the patient extend the great toe. If the artery can be palpated, the needle is placed just laterally to the artery. The needle is advanced toward the tibia, and after negative aspiration, 3 to 5 mL of local anesthetic is injected deep to the fascia to block the deep peroneal nerve (see Fig. 67-19).

### Comments

The deep peroneal nerve travels down the anterior portion of the interosseus membrane of the leg and extends midway between the malleoli onto the dorsum of the foot. At this point, the nerve lies laterally to the extensor hallucis longus tendon and

the anterior tibial artery. It supplies motor innervation to the short extensors of the toes and cutaneous innervation to adjacent areas of the first and second toes.

### Complications

Hematoma and intravascular injection are possible due to the close proximity of the anterior tibial vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

## Saphenous Nerve Block

### Indications

Saphenous nerve blockade is used to diagnose and treat pain disorders of the saphenous nerve distribution in the foot.

### Techniques

After informed consent is obtained, the patient is placed in a prone position with the foot elevated on a pillow. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 25-gauge needle is inserted immediately above and anteriorly to the medial malleolus and advanced to the anterior border of the tibia. After negative aspiration, 3 to 5 mL of local anesthetic is injected over the course of the needle to block the saphenous nerve (see Fig. 67-19).

### Comments

The saphenous nerve is the terminal branch of the femoral nerve. It becomes cutaneous at the lateral aspect of the knee joint and follows the great saphenous vein to the medial malleolus. It supplies cutaneous innervation to the medial aspect of the lower leg anterior to the medial malleolus and the medial aspect of the foot, and may extend as far forward as the metatarsophalangeal joint.

### Complications

Hematoma and intravascular injection are possible due to the close proximity of the great saphenous vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma.

## Intramuscular Nerve (Motor Point) Block

### Indications

Intramuscular nerve blockade is used for diagnostic, prognostic, and therapeutic treatment of non-velocity-dependent muscle tone, flexor spasm, and dystonia.

### Techniques

After informed consent is obtained, the patient is positioned comfortably to allow optimal access to the muscles involved. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A skin wheal is raised over the main muscle bulk of the muscles to be injected. A 1½- to 4-in. (4- to 10-cm) insulated needle is advanced

through the wheal, with a nerve stimulator used to localize the motor nerve branches or motor points. The current is reduced until the minimum current is required to elicit muscle contraction. When the needle tip is within 1 mm of the motor nerve, and after negative aspiration, 1 to 2 mL of 4% to 6% phenol is injected for neurolysis (see Fig. 67-1).

### Comments

Intramuscular nerve or motor point blockade is reported to have duration of effect from 1 to 36 months (median, 11.5 months). No dose-response or dose-duration of effects relationship has been demonstrated for motor point blocks (51,52). The needle is positioned to produce the maximal twitch at the lowest stimulus. The needle is usually adjacent to the nerve when 0.5 to 0.1 mA produces motor stimulation with an insulated needle, and 1 mA with an uninsulated needle. The motor points of each muscle cluster at the midpoint of the muscle fibers.

### Complications

Significant complications are rare with intramuscular nerve injections, and transitory side effects include pain of mild intensity, tenderness and swelling at injection sites, and dysesthesia. Inadvertent neurolysis of a mixed nerve results in painful paresthesia in about 11% of patients.

## COMMON MUSCLE INJECTION TECHNIQUES

### General

Trigger points may occur in any muscle or muscle group of the body. They are commonly found in muscle groups that are routinely overstressed or those that do not undergo full contraction and relaxation cycles. Many trigger points are characterized by pain originating from small circumscribed areas of local hyperirritability involving myofascial structures, resulting in local and referred pain. Pain is aggravated by stretching, cooling, and compression of the affected area, which often gives rise to a characteristic pattern of referred pain (11,12).

Trigger points are best localized by deep palpation of the affected muscle, which reproduces the patient's pain complaint both locally and in the referred zone. Trigger points are usually a sharply circumscribed spot of exquisite tenderness when they are present; passive or active stretching of the affected muscle routinely increases the pain. When compared with equivalent palpation pressure in normal muscle, the trigger point region displays isolated bands, increased tenderness, and referred pain. The muscle in the immediate vicinity of the trigger point is often described as ropey, tense, or a palpable band. The trigger point is injected after palpation of the affected muscle, and the point of maximal tenderness reproducing the pain complaint is identified. When the point of injection has been determined, it is best marked with the tip of a retracted ballpoint pen or needle hub by pressing the skin to reproduce temporary indentation to mark the point of entry. The patient is prepared in a standard aseptic fashion over an area large

enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. The skin and subcutaneous tissue at the injection site are usually not anesthetized.

A 1½- to 2-in. (4- to 5-cm), 22- to 25-gauge needle is advanced into the muscle at the point of maximum tenderness. Before injecting the medication, an attempt should always be made to aspirate to avoid accidental or intravascular injection. Verification that the needle is at the trigger point may be established by the jump sign or reproduction of the pain complaint. Medication should be injected in a fanwise manner in the area of the trigger point.

### Indications for Trigger Point Injections

Trigger point injections may be used to determine the source of pain and to provide maximum pain relief from myofascial pain and to facilitate physical therapy for the stretching of trigger points.

### Contraindications for Trigger Point Injections

Absolute contraindications to trigger point injection include localized infection, a skin condition that prevents adequate skin preparation, the existence of a tumor at the injection site, history of allergy to local anesthetics, gross coagulation defects, septicemia, or an uncooperative patient.

### Complications

The complications associated with trigger point injections include infection, increased pain, local anesthetic overdose, or intravascular injection that can result in CNS toxicity and, in some cases, pulmonary and cardiac arrest. Intraneural injection may result in nerve damage. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be immediately repositioned. Other complications depend on location of the trigger point injection and are discussed separately.

### Techniques

Before the injection, the affected muscle is palpated and the trigger points located and marked. The skin is scrubbed with antiseptic and allowed to dry for 2 minutes. The wearing of sterile gloves is required so that muscle in the sterile field may be palpated throughout the procedure. Before the injection, the trigger point is repalpated and stabilized between the fingers for injection (Fig. 67-20). Routinely, a 1½-in. (4-cm), 21- to 25-gauge needle transverses the skin's subcutaneous tissue and is advanced smoothly into the area of the trigger point.

Aspiration should be done to ensure there is no intravascular penetration. If this does occur, the needle should be repositioned and aspirated to ensure that blood vessels have been avoided, and then the medication is injected. A fanwise manner of injection often results in the longest pain relief, owing to increased distribution of local anesthetic (Fig. 67-21). The needle is then withdrawn, with pressure applied to minimize bleeding.

**FIGURE 67-20.** Trigger point palpation. **A, B:** Palpation and localization of trigger point by rolling beneath two fingers (arrows). **C:** Stabilization of trigger point for injection by spanning with two fingers (arrows). ## SPECIFIC TRIGGER POINT INJECTIONS

### Trapezius

#### Indications

Trigger point injection of the trapezius muscle is used to treat myofascial pain.

#### Techniques

After informed consent is obtained, the patient is placed in the sitting or prone position. The trapezius muscle is palpated. The injection sites are identified as points of maximal tenderness to deep palpation reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large

**FIGURE 67-21.** Fanwise injection technique for trigger point. (From Raj PP. Chronic pain. In: Raj PP, ed. *Clinical Practice of Regional Anesthesia*. New York, NY: Churchill-Livingstone; 1991:491, with permission.)

enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-22).

#### Comments

The referred pain pattern for the upper trapezius is often along the posterior lateral aspect of the neck, as well as peri-articular and temporal regions. The referred pain pattern for the mid trapezius often involves the shoulder and paraspinal region. The referred pain pattern for the lower trapezius usually involves the paraspinal region. The patient should be fully familiar with the stretching program for the trapezius muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

#### Complications

Significant complications are uncommon with trapezius trigger point injections.

### Levator Scapulae

#### Indications

Levator scapulae trigger point injection is a useful diagnostic and therapeutic procedure for myofascial pain.

#### Techniques

After informed consent is obtained, the patient is placed in a sitting or prone position. The levator scapulae muscle is palpated along the attachment at the C1 to C4 vertebrae and the superior angle of the scapulae. The injection sites are identified as points of maximal tenderness to deep palpation reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-23).

#### Comment

The entire body of the levator scapulae muscle should be palpated from origin to insertion and all trigger points injected.

**FIGURE 67-22.** Trapezius. Trigger points and referred pain patterns.

**FIGURE 67-23.** Levator scapulae. Trigger points and referred pain patterns.

Total injection should not exceed maximum safe dosage. The referred pain pattern for the levator scapular muscle often includes a posterior lateral neck and occipital and temporal regions. The patient should be fully familiar with the stretching program for the levator scapulae muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

### Complications

Nerve root blockade may result from improper needle placement or injection of large quantities of local anesthetic in the vertebral region. Intraneural injection may result in nerve damage. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be repositioned immediately.

### Supraspinatus

#### Indications

Supraspinatus injection is a useful diagnostic and therapeutic procedure for myofascial pain.

#### Techniques

After informed consent is obtained, the patient is placed in a sitting or prone position. The supraspinatus muscle is palpated for trigger points from the supraspinous fossa to the humerus. The injection sites are identified as points of maximal tenderness to deep palpation reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration,

the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-24).

### Comment

The referred pain pattern for the supraspinatus muscle often involves the posterior lateral aspect of the shoulder and upper extremity. The patient should be fully familiar with

**FIGURE 67-24.** Supraspinatus. Trigger points and referred pain patterns.

the stretching program for the supraspinatus muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

### Complications

Significant complications are uncommon with supraspinatus trigger point injections.

## Infraspinatus

### Indications

Infraspinatus injection is a useful diagnostic and therapeutic procedure for myofascial pain.

### Techniques

After informed consent is obtained, the patient is placed in the sitting or prone position. The infraspinatus muscle is palpated from the infrascapular fossa of the scapula to the humerus. Trigger points are most often located below the spine of the scapulae. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-25).

**FIGURE 67-25.** Infraspinatus. Trigger points and referred pain patterns.

### Comment

The referred pain pattern for the infraspinatus often involves the deltoid muscle, as well as the area over the lateral shoulder and proximal upper extremity. Pain also may be referred in the infrascapular region. The patient should be fully familiar with the stretching program for the infraspinatus muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

### Complications

Significant complications are uncommon with infraspinatus trigger point injections.

## Pectoralis

### Indications

Pectoralis muscle injection is a useful diagnostic and therapeutic procedure for myofascial pain.

### Techniques

After informed consent is obtained, the patient is placed in the supine position. The pectoralis muscles are palpated. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaints. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-26).

**FIGURE 67-26.** Pectoralis. Trigger points and referred pain patterns.

**Comment**

The referred pain pattern for the pectoralis muscles usually involves the anterior chest wall and breast regions. The patient should be fully familiar with the stretching program for the pectoralis muscle and be instructed in the home program. Failure to include a home stretching program usually results in short-term relief.

**Complications**

Significant complications are uncommon with pectoralis trigger point injections; however, the anatomy of the region, including the close proximity of the thoracic cavity, must be carefully considered. The risk for pneumothorax is reduced by approaching the trigger point with the needle tangential to the thoracic wall.

**Deltoid****Indications**

Deltoid muscle injection is a useful diagnostic and therapeutic procedure for myofascial pain.

**Techniques**

After informed consent is obtained, the patient is placed in the sitting position. The anterior, middle, and posterior components of the deltoid muscle are palpated. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation

**FIGURE 67-27.** Deltoid. Trigger points and referred pain patterns.

of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-27).

**Comment**

The referred pain pattern for the deltoid muscle usually involves the shoulder and proximal upper extremity. The patient should be fully familiar with the stretching program for the deltoid muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

**Complications**

Significant complications are uncommon with deltoid trigger point injections.

**Quadratus Lumborum****Indications**

Quadratus lumborum injection is a useful diagnostic and therapeutic procedure for myofascial pain.

**Techniques**

After informed consent is obtained, the patient is placed in a prone position. The quadratus lumborum muscle is palpated from the 12th rib to the iliac crest and from vertebral attachments L1 to L4 to its lateral border. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-28).

**Comment**

The referred pain pattern for the quadratus lumborum muscle usually involves the iliac crest, hip, and buttock. The patient should be fully familiar with the stretching program for the quadratus lumborum muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

**Complications**

Significant complications are uncommon with quadratus lumborum trigger point injections.

**Paraspinal Musculature****Indications**

The paraspinal muscle injection is a useful diagnostic and therapeutic procedure for myofascial pain.

**FIGURE 67-28.** Quadratus lumborum. Trigger points and referred pain patterns.

### Techniques

After informed consent is obtained, the patient is placed in the prone position. The appropriate thoracic and lumbar regions are palpated. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-29).

### Comment

The referred pain pattern for the thoracic paraspinal muscles often involves the scapular and chest wall region, as well as the lower thoracic paraspinal muscles and abdomen region. The referred pain pattern for the lumbar paraspinal muscles often involves the buttock, iliac crest, and sacroiliac joint region. These muscles involve the erector spinae, semispinalis cervicis, longissimus capitis, longissimus cervicis, longissimus iliocostalis thoracis, iliocostalis lumborum, and semispinalis multifidus.

**FIGURE 67-29.** Paraspinal musculature. Trigger points and referred pain patterns.

The patient should be fully familiar with the stretching program for the affected paraspinal muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

### Complications

Significant complications are uncommon with paraspinal trigger point injections.

### Gluteal

#### Indications

Gluteal muscle injection is a useful diagnostic and therapeutic procedure for myofascial pain.

### Techniques

After informed consent is obtained, the patient is placed in the lateral position with the unaffected side down, or in the prone position. The gluteus maximus, minimus, and medius muscles are palpated. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared

**FIGURE 67-30.** Gluteal trigger points and referred pain patterns.

in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-30).

#### Comment

The referred pain pattern for the gluteus maximus usually involves the sacroiliac joint, hip, and buttock. The referred pain pattern for the gluteus medius often involves the iliac crest, sacroiliac joint, and buttock. The referred pain pattern for the gluteus minimus muscle usually involves the buttock and lateral aspect of the lower extremity. The patient should be fully familiar with the stretching program for the gluteal muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

#### Complications

Significant complications are uncommon with gluteal trigger point injections; however, the anatomy of the region,

including the sciatic nerve, must be carefully considered with these injections. Intraneural injection may result in nerve damage. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be immediately repositioned. Temporary lower extremity weakness is possible from regional spread of the local anesthetic.

### Piriformis

#### Indications

Piriformis muscle injection is a useful diagnostic and therapeutic procedure for myofascial pain.

#### Techniques

After informed consent is obtained, the patient is placed in the lateral Sims' position. The piriformis muscle is palpated from the sacrum toward the hip. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-31).

**FIGURE 67-31.** Piriformis trigger points and referred pain patterns.

### Comments

The referred pain pattern for the piriformis muscle often involves the buttocks, iliosacral region, and posterior hip. The patient should be familiar with the stretching program for the piriformis muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

### Complications

Attention to the anatomy of the sciatic nerve in this region will prevent intraneural injection; otherwise, significant complications are uncommon with trigger point injections. Severe pain on injection suggests the possibility of an intraneural injection, and the needle should be repositioned immediately. Temporary lower extremity weakness is possible from regional spread of the local anesthetic.

## Hip Adductor

### Indications

Hip adductor muscle injection is a useful diagnostic and therapeutic procedure for myofascial pain.

### Techniques

After informed consent is obtained, the patient is placed in the supine position and the affected limb flexed, adducted, and externally rotated. The adductor longus, adductor brevis, and adductor magnus are palpated along the medial aspect of the humerus and thigh. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-32).

### Comment

The referred pain pattern for the adductor muscles of the hip often involves the proximal hip, medial thigh, anterior thigh, and knee. The patient should be fully familiar with the stretching program for the adductor muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief.

### Complications

Significant complications are uncommon with hip adductor trigger point injections.

## Gastrocnemius

### Indications

Gastrocnemius injection is a useful diagnostic and therapeutic procedure for myofascial pain.

### Techniques

After informed consent is obtained, the patient is placed in a supine position. The gastrocnemius and soleus muscles are

**FIGURE 67-32.** Hip adductor trigger points and referred pain patterns.

palpated from the knee to the ankle. The injection sites are identified as points of maximal tenderness to deep palpation, reproducing the patient's pain complaint. This may or may not result in referred pain. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 25-gauge needle is inserted at the point of maximal tenderness and advanced to the area of the trigger point. After negative aspiration, the trigger point area is injected with 4 mL of local anesthetic (Fig. 67-33).

### Comment

The patient should be fully familiar with the stretching program for the gastrocnemius muscle and be instructed in a home program. Failure to include a home stretching program usually results in short-term relief. The referred pain pattern for the gastrocnemius and soleus muscles often involves the posterior knee, calf, heel, and plantar aspect of the foot.

### Complications

Significant complications are uncommon with gastrocnemius trigger point injections.

**FIGURE 67-33.** Gastrocnemius and soleus trigger points and referred pain patterns.

## COMMON JOINT INJECTION TECHNIQUES

### General

The joint is usually injected from the extensor surface at a point where the synovium is closest to the skin. This site minimizes the interference from major arteries, veins, and nerves. When the point of injection has been determined, it is best marked with the tip of a retracted ballpoint pen or a needle hub by pressing the skin to produce a temporary indentation to mark the point of entry. The skin is then prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. The skin and subcutaneous tissue at the injection site may be anesthetized by injecting 1% lidocaine, with or without epinephrine, using a 25- to 30-gauge needle. Alternatively, 5% lidocaine-prilocaine cream may be applied to the skin surface for 15 to 30 minutes prior to skin preparation or a vapocoolant spray may be applied to the skin surface after skin preparation to provide adequate anesthesia (53,54).

A 1½- to 2-in. (4- to 5-cm), 22- to 25-gauge needle is then pushed gently into the joint. Before injecting the medication, an attempt should always be made to aspirate to avoid accidental intravascular injection. After ensuring that the

needle is in the joint space, the medication should be injected in a slow, steady fashion.

Ultrasound guidance has been reported in multiple studies to increase accuracy for needle placement for arthrocentesis and therapeutic steroid injection in joints and tendon sheaths (55–58). One study demonstrated that needle guidance with ultrasound increased the ability to obtain synovial fluid from joints to 97% of patients compared with 32% when using conventional techniques without ultrasound (58).

### Indications for Intraarticular Injection

Intraarticular injections may be used to determine the source of pain as articular or extra-articular and to provide maximal control of inflammation in joints when nonsteroidal anti-inflammatory drug (NSAID) therapy has failed or is contraindicated. Intraarticular injections are indicated to decrease morbidity in self-limited, sterile, inflammatory conditions. Intraarticular injections provide rapid relief of inflammatory pain and facilitate physical therapy of an inflamed joint. Poorly controlled inflammation in more than three joints requires reconsideration of systemic corticosteroids.

The intraarticular injection of hyaluronate for osteoarthritis is a relatively new technique. The viscosupplement acts like synovial fluid to maintain lubrication of the joint. This may be used in early osteoarthritis but does not appear to be an efficacious treatment in advanced osteoarthritis (59).

### Contraindications for Intraarticular Injection

Contraindications must be considered before the injection of any joint. Contraindications to intraarticular injection include overlying soft-tissue sepsis, bacteremia, anatomic inaccessibility, an uncooperative patient, articular instability, septic arthritis, avascular necrosis, osteonecrosis, and neurotrophic joints.

Steroid injection into Charcot's joint is contraindicated because local steroids will not provide significant long-term relief of the symptoms. Avascular necrosis in Charcot's joints has been correlated to corticosteroid injections. Another specific contraindication is injection of an unstable joint unless the instability is appropriately corrected by bracing or surgery. Traumatic arthritis, secondary to fracture through the joint, is another contraindication for steroid injection because the beneficial effects of the steroid injections are not long lasting. Severe osteoporosis in areas around the joint is also a contraindication for injecting steroids.

Injection of joints with surgical implants is relatively contraindicated because these joints are more prone to infection than intact joints and are usually inflamed secondary to infection rather than synovitis. Injection of corticosteroids into a nondiarthrodial joint is rarely of value because there is no synovial sac in which to decrease inflammation.

### Corticosteroids

The amount and type of corticosteroid vary extensively in the musculoskeletal application. The type of corticosteroid chosen is often based on purpose, expected duration, availability,

and preference of the practitioner. Suggested guidelines for maximum amounts with intra articular injections include (60)

- Large joints (e.g., hip)—80 mg triamcinolone acetonide or equivalent
- Medium joints (e.g., knee)—40 mg triamcinolone acetonide or equivalent
- Small joints (e.g., wrist)—20 mg triamcinolone acetonide or equivalent
- Very small joints (e.g., metacarpal phalangeal, zygapophyseal facet)—5 to 10 mg triamcinolone acetonide or equivalent

Suggested guidelines for maximum amounts with bursa injections include

- Large bursa (e.g., subacromial)—20 mg triamcinolone acetonide or equivalent
- Medium bursa (e.g., olecranon)—10 mg triamcinolone acetonide or equivalent
- Small bursa (e.g., anserine, retrocalcaneal)—1 to 5 mg triamcinolone acetonide or equivalent

### Complications

The few complications associated with corticosteroid injections include infection, postinjection inflammation, and tissue atrophy. The occurrence of joint infection is extremely rare with the use of appropriate sterile techniques. Hollander described an incidence of 0.005% in more than 400,000 consecutive injections (10). There is a paucity of research regarding the efficacy and duration of action of various corticosteroids in joint and soft-tissue injections. The use of less soluble corticosteroids (acetate suspensions, e.g., methylprednisolone diacetate, triamcinolone acetonide) results in the steroid remaining in the joint and an assumed longer action. This decreased solubility results in increased possibility of postinjection flare. The use of more soluble corticosteroids (phosphate solutions, e.g., prednisolone sodium phosphate) results in more rapid absorption and an assumed shorter action. This increased solubility results in increased possibility of soft-tissue atrophy (61).

Postinjection inflammation is often secondary to corticosteroid crystal-induced synovitis and may mimic iatrogenic infection. This normally lasts 4 to 12 hours and is treated with NSAIDs and local application of ice. If this persists beyond 24 hours, the patient should be reevaluated to rule out infection. Postinjection flares may last up to 48 hours. The incidence of postinjection inflammation has been estimated at 1% to 6%. Repeated intraligamentous injections may result in calcification and rupture of the ligaments. Penetration of the articular cartilage will result in damage. Traumatic injection is prevented by never injecting against resistance.

Multiple studies on the weight-bearing joints of humans and primates treated with frequent corticosteroid injections have produced conflicting results regarding the adverse effects of corticosteroids on articular cartilage (17,61). However, due to the continued controversy regarding negative effects of corticosteroid injections on cartilage, it is recommended that intraarticular injections should be performed with intervals of

at least 3 months to minimize complications to the cartilage or supporting ligaments.

Tissue atrophy in the area of injection occurs when corticosteroid is placed outside the joint space or leaks from the joint space. If a portion of the injected intraarticular corticosteroid is absorbed into the systemic circulation, the result may be an elevation of blood sugar, hormonal suppression, and brief, generalized improvement in all inflamed joints.

Corticosteroid injections are not recommended immediately after an acute injury or immediately before an athletic event. A patient should have a period of joint immobilization, rest, and protection from further injury after injection (62).

### Techniques

Before the injection, the appropriate landmarks are located and marked. The skin is scrubbed with antiseptic and allowed to dry for 2 minutes. The wearing of sterile gloves is required so that the bony landmarks in the sterile field may be palpated throughout the procedure. Standard sterile technique is required to minimize risk for a septic joint. It is preferable to use single-dose vials of the steroid preparation and local anesthetic agent because this further reduces the risk for infection. A 25- to 27-gauge needle is used with 1% lidocaine, and no epinephrine, to raise a small skin wheal for skin anesthesia. Routinely, a 1½-in. (4-cm), 21- to 25-gauge needle traverses the skin, joint capsule, and synovial lining, sliding smoothly into the joint cavity. One must avoid the periosteum of the bone as well as the articular cartilage during this procedure. Aspiration is done to ensure there is no intravascular penetration. The return of synovial fluid ensures the position of the needle in the joint space; however, often there is minimal to no aspirated fluid. If there is an effusion, the fluid is removed in a slow, steady fashion until all possible joint fluid is aspirated. If the fluid is yellow and clear, the likelihood of infection is minimal, and the corticosteroid may be injected. If the fluid appears turbid, it should be sent for synovial analysis, including culture and sensitivity testing for microorganisms. If infection is suspected, the steroid injection into the joint should be postponed until the culture and sensitivity reports are completed. In addition to examining the color of the fluid, the viscosity of the fluid may be determined by putting a couple of drops of the fluid between the gloved thumb and index finger and stretching it. Normal synovial fluid has a good viscosity and is usually able to stretch for 2 to 2.5 cm. However, if there is an inflammatory process occurring in the joint, the viscosity of the fluid will be significantly decreased with a hazy or cloudy presentation (Table 67-6). The synovial fluid analysis completed in the laboratory may include rheumatoid factor, albumin, complements, protein electrophoresis, glucose level, and cell count with differential. A high white-cell count may indicate an inflammatory process. The fluid for culture and sensitivity should be sent immediately to the laboratory because infections caused by fastidious gonococcal organisms do not survive long in the test tube. Corticosteroids should not be injected into a joint until infection, including that caused by mycobacteria or fungi, has been excluded.

Aspiration from the joint may be impeded by synovial tissue over the end of the needle, intraarticular debris, and excessive joint fluid viscosity. It also may be difficult to aspirate if the tip of the needle is against or imbedded in the articular cartilage or if the needle is not in the joint cavity. It is important to ensure that the entire needle is withdrawn intact, because there have been reports of the separation of the needle from the hub and of needle fracture in articular injections.

The ease with which medication can be injected into the joint provides an indication as to the appropriate placement of the needle. No resistance should be encountered during the injection. If this occurs, the needle should be repositioned and aspirated to ensure that blood vessels have been avoided, and then the medication should be slowly injected. After the medication has been injected, the needle should be cleared with a new syringe containing a small amount of lidocaine or saline. The needle is then withdrawn with pressure applied to minimize bleeding. Joint injections are used primarily to deliver corticosteroids and anesthetic agents to treat inflamed synovium, bursa, and tendon.

Long-acting steroid preparations may induce a crystal synovitis 24 hours after the injection that resolves spontaneously. The patient should be cautioned about possible short-term aggravation of symptoms in the affected joint. It is recommended to infiltrate the subcutaneous tissues and the joint capsule with 2 to 4 mL of 1% lidocaine without epinephrine. When long-acting anesthetic agents are injected into the joint, it is important to advise the patient to limit usage of that joint during the first 24 hours after injection to prevent injury.

## INJECTION OF SPECIFIC SKELETAL STRUCTURES

No consensus exists regarding amounts, types, and mixtures of medications used. Developed familiarity, personal preference, cost, availability, and other factors often influence the use of these agents. Some practitioners promote the injection of a combination of short- and long-acting preparations. The suggested dosages in each of the specific examples in this section are common to many colleagues and other authors.

### Cervical Zygapophyseal Joint

#### Indications

The cervical zygapophyseal joints have been shown to be a potential source of pain from the cranium to the midthoracic spine (63). Cervical facet injections can provide diagnostic as well as therapeutic benefits for patients with a wide variety of head and neck pains.

#### Techniques

After informed consent is obtained, the patient is placed in the prone position with the neck flexed and head turned to the opposite side to open the facet joint. A cushion is placed under the chest to allow neck flexion. The skin entry site lies about two vertebral segments below the target joint. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3-in. (8-cm), 22-gauge spinal needle is advanced superiorly to the inferior margin of the joint. While advancing at a 45-degree angle, care is taken

**TABLE 67.6** Characteristics of Synovial Fluid

Characteristics	Normal	Noninflammatory (E.g., Osteoarthritis, Traumatic Arthritis, Osteochondritis Dissecans, Aseptic Necrosis)	Inflammatory		
			Group I Rheumatoid Arthritis (E.g., Seropositive and Seronegative Spondyloarthritis)	Group II Septic Arthritis (E.g., Bacterial Infection Tuberculosis)	Group III Crystal Synovitis (Gout and Pseudogout)
Clarity	Transparent	Transparent	Transparent to opaque	Opaque, cloudy	Clear with flakes of fibrin
Color	Pale yellow	Yellow or straw	Yellow	Brown/green/yellow/ gray	Yellow
Viscosity	High	High	Low	Very low (may be high with coagulase-positive Staphylococcus)	Low
WBC/mm <sup>3</sup>	<150	<3,000	3–50,000	50–300,000	3–50,000
Predominant cell	Mononuclear (<25% PMN)	Mononuclear (<25% PMN)	Neutrophil (>70% PMN)	Neutrophil (70%–100% PMN)	Neutrophil (>70% PMN)
Crystal	No	No	No	No	Yes
Culture	Negative	Negative	Negative	Often positive	Negative

to ensure the needle is directed over the articular pillars and not allowed to stray medially toward the interlaminar space or excessively laterally. The needle is advanced until contact is made with the articular pillar, either above or below the targeted joint, and then redirected into the joint capsule. Lateral and anteroposterior fluoroscopic views are necessary to ensure that the needle is advanced to the joint midpoint. Injection of contrast media can be used to confirm proper placement in the joint. After negative aspiration, the joint is injected with a 1-mL or less mixture of 6 mg mixture of betamethasone sodium phosphate and betamethasone acetate and local anesthetic (Fig. 67-34). Excessive injectate volume may spread to the epidural space via communication with the joint.

### Comments

Total injected volume should not exceed 1 mL, because the joint volume is usually 1 mL or less. Anterior needle placement should be avoided because the neural foramen, epidural space, and vertebral artery are in close proximity to the anterior surface of the cervical joint.

### Complications

Serious complications from cervical zygapophyseal joint injections are uncommon when meticulous care is given to ensure proper needle placement before injection. Local postinjection pain and light-headedness may occur. Ataxia and dizziness may occur if local anesthetics are used at the more proximal segments, secondary to loss of postural tonic-neck reflexes and

**FIGURE 67-34.** Cervical zygapophyseal joint injection. Fluoroscopic approach for injection (arrows).

proprioceptive input to the cervical muscles. The type of local anesthetic used will determine the duration of these effects. Vertebral artery injection of even small amounts of local anesthetic can cause a seizure; stroke is also possible if particulate steroids are used. Epidural or spinal blockade can occur if the needle placement is medial, resulting in regional blockade, respiratory compromise, and hypotension.

## Costochondral Junction

### Indications

Costochondral junction injection can be very useful as a diagnostic or therapeutic procedure in patients with costochondritis and Tietze's syndrome.

### Techniques

After informed consent is obtained, the patient is positioned in the supine position. The involved costochondral joints are palpated for local tenderness and replication of pain complaint. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 25-gauge needle is inserted at the point of maximum tenderness to the level of costochondral cartilage and withdrawn 1 mm. After negative aspiration, a 2-mL mixture of 40 mg of methylprednisolone acetate or equivalent and local anesthetic is injected into each involved costochondral junction.

### Comments

It is not necessary to advance the needle into the costochondral joint. Infiltration of the superficial tissue over the interosseous groove of the joint at the point of maximal tenderness is usually adequate. Tenderness with costochondritis is often present over more than a single costochondral joint. Tenderness and swelling of a single costochondral joint is found with Tietze's syndrome. The presence of chest wall pain does not exclude underlying heart or lung disease. Similar injection techniques are used for the costoclavicular junction (Fig. 67-35).

### Complications

Serious complications are uncommon with appropriate needle placement. Pneumothorax is possible with inadvertent penetration of the thorax. Most pneumothoraces can be easily treated with administration of supplemental oxygen and close observation and, when necessary, needle aspiration of air. Only those pneumothoraces that result in significant dyspnea or those under tension require chest tube thoracotomy and vacuum drainage.

## Glenohumeral Joint

### Indications

Intraarticular injection of the glenohumeral joint can be used to treat rheumatoid arthritis, inflammatory arthropathy, or adhesive capsulitis.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position, with the shoulder internally rotated. The

**FIGURE 67-35.** Costochondral and costoclavicular junction injection. Approach for costochondral and costoclavicular junction aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:42, with permission.)

glenohumeral joint is palpated by placing the fingers between the coracoid process and humeral head. The joint space can be felt as a groove just lateral to the coracoid process. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 23-gauge needle is inserted 1 fingerbreadth inferiorly and laterally to the tip of the coracoid process. The needle is directed in the anteroposterior plane just lateral to the coracoid process and is advanced into the groove. The needle is very gently manipulated through the joint capsule into the synovial cavity. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration should be completed. After negative aspiration, or if the aspirated fluid is noninflammatory (clear and viscous), a 2- to 3-mL mixture of 20 mg triamcinolone acetonide (or equivalent) and local anesthetic should be administered (Fig. 67-36).

### Comments

Care is required not to direct the needle medially into the neurovascular structures in the axilla.

### Complications

Hematoma and intravascular injection are possible, owing to the close proximity of the axillary vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma. Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Acromioclavicular Joint

### Indications

Intraarticular injection of the acromioclavicular joint is used to treat an inflamed or painful joint, as well as pain secondary to acromioclavicular joint separation.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position. The acromioclavicular joint is palpated by

placing the fingers at the tip of the distal clavicle and medial to the tip of the acromion. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2-cm), 25-gauge needle is inserted at the joint and advanced to the proximal margin of the joint surface. After negative aspiration, the periarticular area is injected with 2 mL of 1% lidocaine for diagnostic purposes. If the local anesthetic provides significant pain relief, the periarticular area should be injected with a 2-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-37A).

**FIGURE 67-36.** Glenohumeral joint injection aspiration and injection. (From Gatter RA. Arthrocentesis technique and intrasynovial therapy. In: Koopman WJ, ed. *Arthritis and Allied Conditions: AA Textbook of Rheumatology*. 13th ed. Baltimore, MD: Williams & Wilkins; 1997:753, with permission.)

**FIGURE 67-37.** Shoulder joint injections. **A:** Approach for shoulder joint aspiration and injection. Acromioclavicular joint injection. **B:** Approach for shoulder joint aspiration and injection. Rotator cuff tendon/subacromial bursa injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:42, with permission.)

### Comments

It is not necessary to advance the needle into the acromioclavicular joint. Infiltration of the superficial tissue over the interosseous groove of the joint at the point of maximal tenderness is usually adequate.

### Complications

Serious complications are uncommon with injection of the acromioclavicular joint.

### Rotator Cuff Tendon and Subacromial Bursa

#### Indications

Corticosteroid injection procedures are used to diagnose and treat rotator cuff tendonitis or subacromial bursitis. These conditions are often due to nonspecific irritation of the subacromial bursa, lesions of the rotator cuff, calcific tendonitis, or rheumatoid arthritis.

### Techniques

After informed consent is obtained, the patient is placed in a sitting position with the arm in the lap. The lateral aspect of the shoulder is palpated for the point of maximal tenderness, usually 1 to 2 cm inferiorly and 1 to 2 cm anteriorly to the angle of the acromion. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in.

(4-cm), 21-gauge needle is inserted below the acromion at the point of maximal tenderness. The needle is gently manipulated under the acromion. Aspiration is attempted until the needle has entered the synovial space. The subacromial bursa is about 1 to 2 cm below the skin between the tip of the acromion process and the head of the humerus. If there is an effusion of the bursa, the aspiration should be completed. After negative aspiration, or if the aspirated fluid is noninflammatory (clear and viscous), a 5-mL mixture of 20 mg of triamcinolone acetonide (or equivalent) and local anesthetic is injected. Half of the mixture should be injected under the acromion in the bursa. The needle should be slightly withdrawn and redirected toward the anterior part of the rotator cuff, and the remainder of the mixture infiltrated (see Fig. 67-37B).

### Comments

Shoulder x-rays may show the locations of calcific deposits. If noted, a 1½-in. (4-cm), 16- to 18-gauge needle is directed to this area and aspiration attempted. Three mL of the mixture is injected at this location. The needle is withdrawn slightly and redirected toward the anterior part of the rotator cuff, and the remainder of the mixture infiltrated. This type of injection is usually uncomfortable, and premedication with codeine or oxycodone should be considered.

### Complications

Corticosteroids should not be injected if there is any suspicion that the bursa is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

### Bicipital Tendon

#### Indications

Peritendinous injection of the bicipital tendon is a useful diagnostic and therapeutic procedure for bicipital tenosynovitis.

### Techniques

After informed consent is obtained, the patient is placed in the seated position with the arm externally rotated and lateral to the medial edge of the humeral head. The bicipital groove is located and the bicipital tendon palpated to determine the area of marked tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 23-gauge needle is inserted along the border of the bicipital tendon. A 6-mL mixture of 20 mg of triamcinolone acetonide (or equivalent) and anesthetic agent is injected 2 mL at a time at the point of maximal tenderness and 1 in. above and below this point along the border of the bicipital tendon sheath (Fig. 67-38).

### Comments

There should be no significant resistance encountered when injecting the tenosynovium. Resistance suggests that the tip of the needle is within the body of the tendon. Steroid injection into the tendon should be avoided.

**FIGURE 67-38.** Bicipital peritendinous injection. Approach for bicipital peritendinous aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:46, with permission.)

### Complications

Injecting directly into the tendon rather than into the peritendinous region may result in damage to the bicipital tendon.

### Lateral Epicondyle of the Elbow

#### Indications

Lateral epicondyle injection is a useful diagnostic and therapeutic procedure for lateral epicondylitis of the elbow (tennis elbow). The condition is usually secondary to occupational or sports-related trauma or recurrent trauma.

#### Techniques

After informed consent is obtained, the patient is placed in the sitting position, with the arm resting on the examination table, palm down, and the elbow flexed to 45 degrees. The elbow is palpated at the junction of the forearm extensor group at its attachment to the bone near the lateral epicondyle to determine the point of maximal tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 23-gauge needle is inserted at the point of maximal tenderness. After negative aspiration, a 5-mL mixture of 10 mg of triamcinolone acetonide acetate (or equivalent)

**FIGURE 67-39.** Lateral epicondyle injection. Approach for lateral epicondyle aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:55, with permission.)

and anesthetic agent is injected at the point of maximal tenderness (Fig. 67-39).

### Comments

The point of maximal tenderness is usually just medial and distal to the lateral epicondyle over the common tendon of the forearm extensor group at its attachment to the bone.

### Complications

Serious complications are uncommon with injection of the lateral epicondyle of the elbow.

### Medial Epicondyle of the Elbow

#### Indications

Medial epicondyle injection is a useful diagnostic and therapeutic procedure for medial epicondylitis (golfer's elbow or tortilla elbow).

#### Techniques

After informed consent is obtained, the patient is placed in the sitting position, with the arm resting on the examination table, palm up, and the elbow flexed to 45 degrees. The elbow is palpated at the junction of the forearm extensor group at its attachment to the bone at the lateral epicondyle to determine the point of maximal tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure.

A 1½-in. (4-cm), 23-gauge needle is inserted at the point of maximal tenderness. After negative aspiration, a 5-mL mixture of 10 mg of triamcinolone acetonide acetate (or equivalent) and anesthetic agent is injected at the point of maximal tenderness.

### Comments

The point of maximal tenderness is usually just lateral and distal to the medial epicondyle over the common tendon of the forearm flexor group at its attachment to the bone.

### Complications

Avoid injecting the ulnar nerve in the groove just behind the medial epicondyle.

## Olecranon Bursa of the Elbow

### Indications

Olecranon bursa injection is a useful diagnostic and therapeutic procedure for olecranon bursitis. This condition is usually secondary to trauma or rheumatoid arthritis.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the hand on the lap. The olecranon process of the ulna is palpated for swollen bursa. The point of maximum swelling is marked. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21-gauge needle is inserted at the most prominent part of the olecranon bursa. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the bursa, the aspiration is completed. After negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the bursa is injected with a 3-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-40).

### Comments

This procedure may require an 18-gauge needle to aspirate the bursa with highly viscous fluid.

### Complications

Corticosteroids should not be injected if there is any suspicion that the bursa is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Radiohumeral Joint (True Elbow Joint)

### Indications

Radiohumeral joint injection is used to diagnose and treat the painful and swollen elbow due to rheumatoid arthritis or non-specific inflammatory arthritides.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the elbow flexed to 90 degrees. The lateral

**FIGURE 67-40.** Olecranon injection. Approach for olecranon aspiration and injection. (From Akins CM. Aspiration and injection of joints, bursae, and tendons. In: Vander Salm TJ, Cutler BS, Brownell Wheeler H, eds. *Atlas of Bedside Procedures*. Boston, MA: Little, Brown; 1979:357, with permission.)

epicondyle and posterior olecranon are palpated. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21- to 23-gauge needle is inserted into the groove just above and lateral to the olecranon process, just below the lateral humeral epicondyle, and posterior to the head of the radius. The needle is gently manipulated into the joint. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. After negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 5-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-41).

### Comments

The connective tissue surrounding the elbow joint should be evaluated as a possible source of pain before injection of the radiohumeral joint.

### Complications

Corticosteroids should not be injected if there is any suspicion that the bursa is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Carpal Tunnel

### Indications

Injection of the carpal tunnel is used to treat inflammation of the tissue of the tunnel resulting in median nerve entrapment.

**FIGURE 67-41.** Radiohumeral joint injection. Approach for radiohumeral joint aspiration and injection. (From Gatter RA. Arthrocentesis therapy and intra-synovial injection. In: Koopman WJ, ed. *Arthritis and Allied Conditions: A Textbook of Rheumatology*. 13th ed. Baltimore, MD: Williams & Wilkins; 1997:714, with permission.)

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the arm resting on the examination table. The wrist is positioned with the hand dorsiflexed over a towel. The injection site is on the volar wrist surface just proximal to the distal wrist crease between the palmaris longus and flexor carpi radialis tendons. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 23- to 25-gauge needle is directed distally at an angle of 60 degrees to the skin and gently manipulated through the flexor retinaculum ligament into the carpal tunnel. The tunnel is about 1 to 2 cm from the skin in this

position. After negative aspiration, the carpal tunnel is injected with a 1-mL mixture of 10 mg of triamcinolone acetonide acetate (or equivalent) and local anesthetic (Fig. 67-42).

### Comments

Anesthesia in the distribution of the median nerve verifies injection into the carpal tunnel. These paresthesias may last for 1 to 2 weeks.

### Complications

The median nerve should not be injected. The patient will normally report a sharp, electrical sensation when the needle tip is against the median nerve, and excruciating pain if the needle

**FIGURE 67-42.** Carpal tunnel injection. Approach for carpal tunnel aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:59, with permission.)

tip pierces the median nerve. If either of the above occurs, withdraw slightly and continue the procedure. The volume injected into the carpal tunnel should be kept to a minimum to reduce postinjection discomfort.

## Wrist Joint

### Indications

Wrist joint injection is a useful diagnostic and therapeutic procedure for inflammation due to rheumatoid arthritis and other inflammatory arthritides.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the arm resting on the examination table. The hand is placed palm down with the wrist positioned over a rolled towel. The wrist joint is approached from the dorsal aspect. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 23-gauge needle is inserted between the distal radius and ulna on the ulnar side of the extensor pollicis longus tendon. The needle is gently manipulated into the joint cavity to a depth of about 1 to 2 cm. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. After negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 2- to 3-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-43).

### Comments

Many of the synovial joints of the wrists are interconnected. No significant resistance should be encountered. If resistance is encountered, the needle may not be in the joint cavity. Scapholunate dislocation, carpal instability, avascular necrosis, or other etiology of chronic conditions should be considered before injection. Elastic bandage or splint immobilization for 24 hours after injection may decrease discomfort.

### Complications

Intraneural injection may result in nerve damage. Hematoma and intravascular injection are possible due to the close proximity of the vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma. Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, then it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Abductor Tendon of the Thumb

### Indications

Abductor tendon of the thumb injection is a useful therapeutic procedure for tenosynovitis of extensor pollicis brevis and abductor hallucis longus (de Quervain's syndrome) usually

**FIGURE 67-43.** Wrist joint injection. Approach for wrist joint aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:61, with permission.)

associated with repetitive trauma disorder. This procedure involves injection of common tendon sheath of the long abductor and short extensor tendons of the thumb.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the arm resting on the examination table. The forearm is placed on the ulnar side midway between supination and pronation. The wrist is held in ulnar deviation over a rolled towel, stretching the tendons over the radial styloid. Tendons are palpated for the point of maximal tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (3-cm), 23-gauge needle is inserted in a proximal direction, parallel to the tendon at a tangential angle, aiming for the point of maximal tenderness. Once the needle is in the tenosynovium, 0.25 to 0.5 mL of local anesthetic can be injected with a tuberculin syringe without significant resistance. This results in a small sausage-shaped swelling along the length of the tendons. At this point, the syringe containing only local anesthetic is disconnected, and another syringe is used to inject the peritendinous area with a 2-mL mixture of 5 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-44).

**FIGURE 67-44.** Abductor tendon sheath thumb injection. Approach for abductor tendon sheath of the thumb aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:58, with permission.)

### Comments

There should be no significant resistance encountered in the tenosynovium. There will be resistance encountered by the plunger of the syringe if the needle is in the tendon. Steroid injection into the tendon should be avoided.

### Complications

Injecting directly into the tendon rather than into peritendinous region can result in damage to the abductor tendon of the thumb.

## First Metacarpal Joint

### Indications

First metacarpal joint injection is used to treat pain and inflammation secondary to osteoarthritis.

### Techniques

After informed consent is obtained, the patient is placed in a sitting position with the arm resting on the examination table. The forearm is placed on the ulnar side midway between supination and pronation, with the thumb adducted and held in flexion with the palm. The first metacarpal along the dorsal aspect to the groove at its proximal end is palpated. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm) needle is inserted at the point of maximal tenderness. The needle is advanced into the joint space. Aspiration is attempted until the needle has entered the synovial space. After negative aspiration or if there is an effusion of the joint, the aspiration is completed. If negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 1- to 3-mL mixture of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-45).

### Comments

Piercing the radial artery and extensor pollicis tendon should be avoided.

### Complications

Radial artery injury, extensor pollicis tendon injury, and increased pain for 1 to 3 days are uncommon, but may result from this injection. Hematoma and intravascular injection are possible due to the close proximity of the axillary vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma. Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Interphalangeal Joint

### Indications

Interphalangeal joint injection is used as a therapeutic procedure to treat inflammation of the metacarpal phalangeal and interphalangeal joints due to rheumatoid arthritis and other inflammatory arthritides.

**FIGURE 67-45.** First metacarpal joint injection. Approach for first metacarpal joint aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:63, with permission.)

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the arm resting on the examination table. The hand is placed with the joint extended for approach from the lateral or medial aspect, with slight traction applied to the finger. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1-in. (2.5-cm), 25- to 27-gauge needle is inserted at the borders of the joint and advanced gently to the joint capsule. Pericapsular injection without attempting to enter the joint is appropriate. The pericapsular area is injected with a 1-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-46).

### Comments

No effort should be made to aspirate fluid unless infection is suspected.

### Complications

Serious complications are uncommon with appropriate needle placement.

## Lumbar Zygapophyseal Joint

### Indications

The lumbar zygapophyseal (facet) joints have been shown to be a potential source of pain involving the low back and buttocks. Facet joint injections can provide diagnostic as well as therapeutic benefits for patients with low back pain.

### Techniques

After informed consent is obtained, the patient is placed in the prone position with a pillow under the pelvis to flatten the lumbar curve. The lumbar spine is palpated for the point of maximum tenderness. The patient is prepared in a standard

**FIGURE 67-46.** Interphalangeal joint injection. Approach for first metacarpal joint aspiration and injection. (Reprinted with permission from Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:64, with permission.)

aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3-in. (8-cm), 22-gauge needle is inserted at the point of maximum tenderness. The needle is advanced to the joint, with care taken to ensure that the needle is directed over the articular pillars and not allowed to stray medially toward the interlaminar space or excessively laterally. The needle is advanced until contact is made with the articular pillar, either above or below the targeted joint, and then redirected into the joint capsule. Lateral and anteroposterior fluoroscopy views are necessary to ensure that the needle is advanced to the joint midpoint. Injection of contrast medium may be used to confirm proper placement in the joint. After negative aspiration, the joint is injected with a 1-mL or less mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-47).

### Comments

Total injected volume should not exceed 1 mL, because joint volume is usually 1 mL or less. Anterior needle placement should be avoided because the dural sleeve, spinal cord, and epidural space are in close proximity to the anterior surface of the cervical joint.

### Complications

Serious complications from lumbar zygapophyseal joint injections are uncommon when meticulous care is given to ensure proper needle placement before injection. Local postinjection pain may occur. Intravascular injection of local anesthetic may cause a seizure. Epidural or spinal blockade can occur if the needle placement is medial, resulting in regional blockade, respiratory compromise, and hypotension.

**FIGURE 67-47.** Lumbar facet joint injection. Fluoroscopic approach for lumbar facet joint injection (arrows).

## Sacroiliac Joint

### Indications

Sacroiliac joint injection is used to treat inflammation of the sacroiliac joints secondary to trauma, rheumatoid arthritis, degenerative joint disease, or stress secondary to mechanical changes in posture or gait.

### Techniques

After informed consent is obtained, the patient is placed in the prone position. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 6-in. (16-cm), 22-gauge needle is inserted. The needle is advanced under fluoroscopy to the joint. After negative aspiration, joint penetration is confirmed with 1 mL of diatrizoate meglumine injection USP 60% (Renografin-60). After needle location is confirmed, a 1.5 to 2.0 mL (64) mixture of 40 mg of methylprednisolone acetate (or equivalent) and local anesthetic is injected (Fig. 67-48).

### Comments

The sacroiliac joint is difficult to aspirate, owing to the depth and bony structures. Fluoroscopic guidance with the use of contrast media is recommended. It is rare to aspirate fluid from this joint.

### Complications

Serious complications are uncommon with appropriate needle placement.

## Coccygeal Junction

### Indication

Infiltration of the coccyx region can be useful as a therapeutic procedure in coccydynia after exclusion of infection or other significant pathology.

### Techniques

After informed consent is obtained, the patient is positioned in the lateral Sims' position with the left side down for right-handed clinicians. With the upper leg flexed, the buttocks are separated, allowing easy access to the sacrococcygeal junction. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. The area of tenderness is localized by palpating from the tip of the coccyx to the sacrococcygeal junction. The palpating hand is kept in position, and a 1½-in. (4-cm), 21-gauge needle is inserted at the point of maximal tenderness perpendicular to the skin. After negative aspiration, a 3-mL mixture of 20 mg of methylprednisolone acetate or equivalent and local anesthetic is injected into the tender area using a fan pattern (Fig. 67-49).

### Comments

It is not necessary to advance the needle into the sacrococcygeal junction. Infiltration of the superficial tissue at the point of maximal tenderness is usually adequate.

**A**

**B**

**FIGURE 67-48.** Sacroiliac joint injection. **A:** Fluoroscopic approach for right sacroiliac joint. **B:** Approach for sacroiliac joint injection. (From Buckley FP. Regional analgesia with local anesthetics. In: Loeser JD, ed. *Bonica's Management of Pain*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:1893–1952, with permission.)

**FIGURE 67-49.** Coccygeal junction injection. Approach for coccygeal junction injection. (From Willis RJ. Caudal epidural blockade. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 3rd ed. Philadelphia, PA: JB Lippincott; 1998:373, with permission.)

### Complications

Perianal numbness may be noted for 24 hours after injection. Serious complications are uncommon with appropriate needle placement.

### Hip Joint

#### Indications

Hip joint intraarticular injection is used to treat inflammation of the hip secondary to rheumatoid arthritis or osteoarthritis.

#### Techniques

After informed consent is obtained, the patient is placed in the supine position with the leg straight and externally rotated. A point is marked at 2 cm below the anterosuperior spine of the ilium and 3 cm laterally to the palpated femoral pulse at the level of the superior edge of the greater trochanter. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3.5-in. (9-cm), 21-gauge needle is inserted at the mark in the posterior medial direction at an angle 60 degrees to the skin. The needle is advanced through the tough capsular ligaments to the bone and slightly withdrawn. Under fluoroscopy, contrast medium is injected to confirm appropriate needle placement. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. After negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 2- to 4-mL mixture of 20 mg triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-50).

#### Comments

The hip joint is difficult to aspirate or inject due to the depth and limited landmarks. Fluoroscopic guidance with the use of contrast media is recommended. It is rare to aspirate fluid from this joint.

### Complications

Avascular necrosis of the hip has been reported as a result of repeated intraarticular injection of corticosteroids. Hematoma and intravascular injection are possible, owing to the close

proximity of the femoral vessels. If an arterial puncture occurs, prolonged direct pressure is usually adequate to prevent the development of a hematoma. Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

### Trochanteric Bursa

#### Indications

Trochanteric bursa injection is used to diagnose and treat bursitis of the hip. This often presents as pain in the lateral thigh during ambulation. Pain may be elicited by placing the hip in external rotation and abduction.

#### Techniques

After obtaining informed consent, the patient is positioned lying on the side and facing the clinician, with the painful hip exposed. The hips and knees are flexed and the affected

**FIGURE 67-50.** Hip joint injection. Approach for hip joint aspiration and injection. Lateral approach. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:83, with permission.)

hip adducted. The protuberance of greater trochanter on the lateral aspect of the thigh is palpated for the point of maximal tenderness. This is usually two fingerbreadths below the tip of the trochanter. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 3-in. (8-cm), 21-gauge needle is inserted perpendicular to the skin at the point of maximal tenderness. The needle is advanced with aspiration attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. If the aspirated fluid is non-inflammatory (clear and viscous), the bursa should be injected with a 3-mL mixture of 20 mg of triamcinolone acetonide (or equivalent) and local anesthetic. If unable to enter the synovial space, the needle is advanced to the bone and then withdrawn 2 mm. After negative aspiration, a 3 mL mixture of 20 mg of triamcinolone acetonide (or equivalent) and local anesthetic is injected (Fig. 67-51).

### Comments

The clinician should consider other causes of pain if the problem persists after bursa injection and appropriate rehabilitation.

### Complications

Corticosteroids should not be injected if there is any suspicion that the bursa is infected. If the fluid appears infected, it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

## Abductor Tendon of the Hip

### Indications

Injection of the abductor tendon is a useful diagnostic and therapeutic procedure for tendonitis at the insertion of the gluteal musculature into the greater trochanter.

**FIGURE 67-51.** Trochanteric bursa injection. (From Akins CM. Aspiration of joints, bursae, and tendons. In: Vander Salm TJ, Cutler BS, Brownell Wheeler H, eds. *Atlas of Bedside Procedures*. Boston, MA: Little, Brown; 1988:359, with permission.)

### Techniques

After informed consent is obtained, the patient is positioned lying on the side facing the clinician with the painful hip exposed. The hips and knees are flexed and the affected hip adducted. The hip is palpated above the tip of the trochanter to determine the point of maximal tenderness. A 3.5-in. (9-cm), 21-gauge needle is inserted at the point of maximal tenderness and directed toward the tip of the greater trochanter, approximating the insertion of the gluteal fasciae. The needle is advanced vertically to a depth that would reach the hip abductor tendon. This depth would vary from one patient to another, which is estimated by palpation of the hip abductor tendon. In obese patients, a lumbar puncture needle would have to be used to reach the tendon area. After negative aspiration, the area of maximal tenderness is injected with a 10-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic.

### Comments

The injection is not placed into the tendon but rather into the peritendinous region. Wide infiltration with a corticosteroid and local anesthetic mixture is recommended. Tender points in the vicinity of the hip joint are often associated with osteoarthritis of the hip. Injection of these sites may provide significant pain relief.

### Complications

Injecting directly into the tendon rather than into the peritendinous region may result in damage to the abductor tendon of the hip.

## Knee Joint

### Indications

Intraarticular corticosteroid injection of the knee joint is used to treat noninfective inflammatory joint disease secondary to rheumatoid arthritis, seronegative spondyloarthritides, or the chondrocalcinosis inflammatory phase of osteoarthritis.

### Techniques

After informed consent is obtained, the patient is placed in the sitting position with the knee flexed to 90 degrees. The patellar tendon is palpated and the middle of the patellar tendon is marked. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21-gauge needle is inserted horizontally and advanced to the intercondylar notch. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. After negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 2-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-52).

### Comments

An alternate approach may be used to access the suprapatellar pouch, which is continuous with the synovial space of the

**FIGURE 67-52.** Knee joint injection. Approach for knee joint aspiration and injection. Anterior approach. (From Akins CM. Aspiration and injection of joints, bursae, and tendons. In: Vander Salm TJ, Cutler BS, Brownell Wheeler H, eds. *Atlas of Bedside Procedures*. Boston, MA: Little, Brown; 1979:363, with permission.)

knee. The patient is placed in the supine position with the leg fully extended. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. Throughout the procedure, the patella should be grasped between the examiner's thumb and forefinger and should be able to be moved from one side to another to ensure that the quadriceps muscle is relaxed. A 1½-in. (4-cm), 21-gauge needle is inserted horizontally into the suprapatellar pouch at a point lateral and posterior to the patella at the level of the cephalad edge. A small amount of pressure is placed on the patella, pushing it to the side of needle insertion. This improves the ability to direct the needle during advancement (Fig. 67-53). The patient should be advised to minimize walking activity for 24 hours after injection, to minimize dispersion of the corticosteroid from the joint. If fluid is exceptionally viscous, a 1½-in., 18-gauge needle may be required to aspirate the joint.

### Complications

Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, then it should be sent for culture and sensitivity and the patient treated appropriately for the infection. It is contraindicated to inject the joint in a person with hemophilia, unless the risk for intraarticular bleed has been minimized. Corticosteroid injection into the knee joint may impair epiphyseal growth in children, resulting in a significant leg-length discrepancy.

**FIGURE 67-53.** Knee joint injection. Medial approach to suprapatellar pouch for knee joint aspiration and injection. Note connection between suprapatellar pouch and main synovial cavity. (From Gatter RA. Arthrocentesis technique and intrasynovial therapy. In: Koopman WJ, ed. *Arthritis and Allied Conditions: A Textbook of Rheumatology*. 13th ed. Baltimore, MD: Williams & Wilkins; 1997:752, with permission.)

## Anserine Bursa of the Knee

### Indications

Anserine bursa injection is a useful diagnostic and therapeutic procedure in bursitis resulting from osteoarthritis or direct trauma. Pain is noted inferior to the anterior medial surface of the knee when climbing stairs. Pain is reproduced with the knee in flexion-extension while internally rotating the leg.

### Techniques

After informed consent is obtained, the patient is placed in the supine position with the knee in extension. The knee is palpated for the point of maximal tenderness over the medial tibial flare. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21-gauge needle is inserted perpendicular to the skin and at the point of maximal tenderness. The needle is advanced to the periosteum and withdrawn slightly. After negative aspiration, a 4-mL mixture of 2 mg of triamcinolone acetonide (or equivalent) and local anesthetic is injected (Fig. 67-54).

### Comments

The anserine bursa is one of the most common bursae to become inflamed in the lower extremity. Kneepads are recommended for athletes with anserine bursitis secondary to trauma.

### Complications

Serious complications are uncommon with injection of the anserine bursa.

## Tibiotalar Joint

### Indications

Tibiotalar joint injection is a useful therapeutic procedure with inflammation secondary to osteoarthritis, rheumatoid arthritis,

**FIGURE 67-54.** Anserine bursa injection. Approach for anserine bursa aspiration and injection. (From Akins CM. Aspiration of joints, bursae, and tendons. In: Vander Salm TJ, Cutler BS, Brownell Wheeler H, eds. *Atlas of Bedside procedures*. Boston, MA: Little, Brown; 1988:361, with permission.)

or chronic pain from instability. Pain most often occurs with ankle extension and flexion with weight bearing.

### Techniques

After informed consent is obtained, the patient is placed in the supine position with the leg extended and the ankle extended over the end of the examination table. The area just anterior to the medial malleolus at the articulation of the tibia and the talus should be palpated and marked. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21-gauge needle is inserted at the mark perpendicular to the skin. The needle is advanced slightly laterally, penetrating the capsule of the joint. The needle is directed into the tibiotalar joint to a depth of about 2 to 3 cm. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. After negative aspiration or if the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 2-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-55).

### Comments

Injection of this joint is usually secondary to osteoarthritis resulting from trauma or from repetitive overuse injury such as from ballet dancing. If the swelling and tendonitis are around the lateral aspect of the joint, entry is accomplished just below the lateral malleolus. Gout is not an indication for injecting this joint.

### Complications

Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, then it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

### Subtalar (Talocalcaneal) Joint

#### Indications

Subtalar joint injection is used to treat inflammation secondary to rheumatoid arthritis and other inflammatory arthritides.

**FIGURE 67-55.** Tibiotalar joint injection. Approach for tibiotalar joint aspiration and injection. (From Steinbrocker O, Neustadt DH. *Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders*. Hagerstown, MD: Harper & Row; 1972:89, with permission.)

### Techniques

After informed consent is obtained, the patient is placed in the prone position with the feet extending over the end of the examination table and the foot flexed to about 90 degrees. The location of the subtalar joint, about 1 to 2 cm distal to the tip of the lateral malleolus and posterior to the sinus tarsus, should be palpated and marked. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 21-gauge needle is inserted perpendicular to the skin at the mark and advanced medially into the subtalar joint. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. If the aspirated fluid is noninflammatory (clear and viscous), the joint should be injected with a 2-mL mixture of 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic (Fig. 67-56).

### Comments

Injection of this joint is usually secondary to osteoarthritis resulting from trauma or from repetitive overuse injury such as from ballet dancing. Gout is not an indication for injecting this joint.

### Complications

Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, then it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

**FIGURE 67-56.** Subtalar (talocalcaneal) joint injection. Approach for subtalar (talocalcaneal) joint aspiration and injection. (From Gatter RA. Arthrocentesis technique and intrasynovial therapy. In: Koopman WJ, ed. *Arthritis and Allied Conditions: A Textbook of Rheumatology*. 13th ed. Baltimore, MD: Williams & Wilkins; 1997:752, with permission.)

### Retrocalcaneal Bursa

#### Indications

Retrocalcaneal bursa injection is a useful therapeutic procedure for bursitis secondary to repetitive overuse disorder or rheumatoid arthritis.

#### Techniques

After informed consent is obtained, the patient is situated in the side lying position. The lateral malleolus and the Achilles tendon are palpated. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 23- to 25-gauge needle is inserted between the lateral malleolus and the Achilles tendon perpendicular to the skin. The needle is advanced slowly to about half the thickness of the width of the Achilles tendon. After negative aspiration, a 2-mL mixture of 2 mg of triamcinolone acetonide (or equivalent) and local anesthetic is injected (Fig. 67-57).

### Comments

This disorder may be seen in runners as they increase mileage early in the season or from an improperly fitting running shoe.

### Complications

Corticosteroids should not be injected if there is any suspicion that the bursa is infected. If the fluid appears infected, then it should be sent for culture and sensitivity and the patient treated appropriately for the infection.

**FIGURE 67-57.** Retrocalcaneal bursa injection. Approach for retrocalcaneal bursa aspiration and injection. (From Gross J, Fetto J, Rosen E. *The Ankle and Foot*. Cambridge, MA: Blackwell Science; 1996:393, with permission.)

## Plantar Heel Fascia

### Indications

Plantar heel fascia injection is used to treat inflammation at the insertion of the long plantar ligament at the anterior aspect of the calcaneus, secondary to chronic overuse disorder or spondyloarthritides.

### Techniques

After informed consent is obtained, the patient is placed in the prone position with the feet extending over the end of the examination table. The plantar aspect of the heel is palpated in the area of the attachment of the plantar fascia to the calcaneus to determine the point of maximal tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. A 1½-in. (4-cm), 23- to 25-gauge needle is inserted at the point of maximum tenderness on the plantar surface of the heel, perpendicular to the skin. The needle is gently advanced until the tip touches the underlying bone and then is withdrawn 2 mm. After negative aspiration, a 2-mL mixture of 20 to 10 mg of triamcinolone acetonide (or equivalent) and local anesthetic is injected. If proper palpation of the point of maximal tenderness is difficult, one half of the mixture of local anesthetic and corticosteroid should be injected into the region of maximal tenderness and the remainder injected in a fanwise manner around the plantar fascia attachment (Fig. 67-58A).

### Comments

This is a significantly painful procedure with or without cutaneous anesthesia. After injection, the patient is discouraged from excessive walking until the local anesthetic wears off and is encouraged to wear a heel cushion inside the shoe.

## Complications

Serious complications are uncommon with appropriate needle placement.

## Metatarsophalangeal Joint

### Indications

Metatarsophalangeal joint injection is a useful procedure in the treatment of joint inflammation secondary to rheumatoid arthritis.

### Techniques

After obtaining informed consent, the patient is positioned for optimal access to the dorsal surface of the foot. The metatarsophalangeal joints are palpated for swelling and point tenderness. The patient is prepared in a standard aseptic fashion over an area large enough to allow palpation of landmarks, and sterile technique is used throughout the procedure. Light traction is applied to the toe of the joint to be injected. A ½- to 1-in. (1.5- to 2.5-cm), 25-gauge needle is inserted perpendicular to the skin, directly into the joint space. Aspiration is attempted until the needle has entered the synovial space. If there is an effusion of the joint, the aspiration is completed. After negative aspiration or the aspirated fluid is noninflammatory (clear and viscous), the joint is injected with a 0.5-mL mixture of 5 mg of triamcinolone acetate (or equivalent) and local anesthetic (see Fig. 67-58B).

### Comments

These joints are often limited to 0.5 mL of solution. The first metatarsophalangeal joint may be approached from the medial side with the needle advanced tangentially under the extensor tendon.

## Complications

Corticosteroids should not be injected if there is any suspicion that the joint is infected. If the fluid appears infected, then
